MUSEUMS AND ART GALLERIES AS A NATIONAL SERVICE

A PUBLICATION of considerable importance to museum and art gallery officials and committees, and all municipal and county authorities contemplating the establishment or reorganization of museums and art galleries, appears in the *Museums Journal* of June 1945, pp. 33–45. Entitled "Museums and Art Galleries in the Post-war Period: a Survey and Proposals by the Museums Association", it sets forth the contents of a document submitted last May to the Minister of Reconstruction after a discussion had taken place between representatives of the Ministry and the Museums Association, London.

This document surveys the present position of the museums and art galleries of Great Britain, and makes far-reaching proposals for their future development. It points out the general inadequacy of these services outside London, and calls for an all-round improvement of existing buildings, administration, staffs and finance, wherever necessary. The financial figures given for 1938 are illuminating: in that year, approximately £1,000,000 was spent on the thirteen national institutions in London, while the 770 institutions in other parts of the country received about £450,000. In other words, the average expenditure on museums and art galleries in the provinces only amounted to about threepence per head of the population. These figures do not include the national museums in Edinburgh and Cardiff which, like those in London, are supported by the State. Further analysis shows that, of the provincial museums, as many as 470 were—and presumably continue to be—in receipt of incomes of less than £300. (Nearly half of these, however, are attached to libraries or colleges and have not a separate income, so that their financial position may not be so bad as at first appears.) Nevertheless, these figures serve to expose a further unsatisfactory condition relative to the welfare of the average British museum, namely, the entirely disproportionate and low rates of pay for work which requires a high standard of education, specialized training and technical ability. Except in the national museums and in those of the larger provincial centres, a director's or curator's salary, for example, is (to quote from the document), "always among the lowest given to the chief officers of the corporation, and it is more often than not smaller than that given to deputies in other departments". In the case of officials of smaller museums, it is sometimes even less than that allotted to the local dustmen! Consequently, little but a devotion to the work encourages men and women of the right calibre to take up museum or art gallery work at the present time.

Section V of the document is particularly concerned with the ways and means of improvement of the museum services of Britain as a whole. It is recognized that the much-needed development rests upon the provision of adequate funds; for new or reconstructed buildings, staffs adequate in training and numbers, and a wide range of facilities and equipment are involved. Suggestions are made regarding the method of financial support, the most favoured being the establishment of a Museum and Art Gallery Grants Board on the lines of the University Grants Committee. The Board would consist of experts sympathetic with museum and art gallery problems, and these would "assess schemes, allocate grants, and impose conditions which, under a scheme of inspection, would ensure the maintenance of suitable standards, and so assist in raising the status of museums and art galleries throughout the country".

Museums and art galleries form cultural centres: they educate, and provide for the intelligent use of leisure; they are in contact with a very wide public, and are, therefore, in a particularly favourable position for the diffusion of knowledge based on scientific principles: they have (or should have), therefore, a very definite place within any intelligent community. In this light, the direct appeal for government support and encouragement which this document puts forward is worthy of the closest consideration.

WAVE-LENGTHS FOR EUROPEAN BROADCASTING

THE wave-lengths or frequencies used by broadcasting stations in Europe in normal times were the result of discussions and conferences held under the auspices of the International Broadcasting Union formed about twenty years ago. It was as a result of the activities of this Union that the Lucerne plan was formulated and put into practical operation during the night of January 14–15, 1934, when a general re-distribution of wave-lengths of European broadcasting stations was conducted by the responsible organizations. In April 1939 a revised plan was drawn up in the form of the Montreux Convention, which was signed by the representatives of thirty-one States; and this plan provided for certain changes in wave-length and power of European broadcasting stations to come into effect in March 1940. Although the operation of this plan was in any case prevented by the War, it is doubtful whether it would have been successful had it been applied; for, as Sir Noel Ashbridge remarked in his presidential address to the Institution of Electrical Engineers in 1941, these international conferences were rendered very difficult by the various political influences involved. Sir Noel expressed the hope that, after the War, it would be possible for a well-based wave-length plan for Europe to be built up on rational principles with due regard to technical facts.

It is with the view of rendering assistance towards this objective that the Radio Industry Council has recently issued a report entitled "Post-War European Broadcasting", prepared by the technical committee of the British Radio Equipment Manufacturers' Association (Radio Industry Council, 59 Russell Square, London, W.C.1). This report outlines a new proposal, based upon technical considerations and on appreciation of the ordinary listener's requirements, for the allocation of wave-lengths among the thirty European countries. The proposal aims at providing for every nation at least one, and in most cases two, programmes which adequately cover the entire country; in addition, a system of regional programmes would be provided to meet local requirements, and in particular the major language groups in each country. The whole scheme would also provide for every listener good signals from some foreign stations in addition to his own national and regional programmes.

For the plan to be successful in attaining these objectives, it is clearly necessary to arrange wave-lengths in relation to the location and power of the transmitters, so as to minimize interference between any two stations, and to permit reasonable quality of reproduction from receivers in all parts of the service area of each station. Power as well as wave-length would have to be specified in order to ensure good service over each area, while still avoiding serious interference with other transmitters.

As a basis for the proposals put forward in the report, the radius of the service area or coverage of a broadcasting station is defined as the distance to which the ground-wave signal is greater than 2 mV./metre, and the ionospheric or sky-wave signal which causes fading is never more than a certain value to be selected on the basis of experience. Based upon such assumptions, the report states that the primary service area of medium-wave broadcasting stations is a circle, the radius of which in miles is approximately equal to one-quarter of the wave-length in metres. Proceeding along these lines, the main national allocations are obtained by using the whole of the existing long-wave broadcasting band of 156–288 kc./s. (wave-lengths 1,040–1,920 m.) together with the extension envisaged in the Montreux plan of 344–432 kc./s. (695–873 m.). In this extended long wave-band, sufficient frequency allocations are proposed, at intervals of 11 kc./s. between stations, to provide two national programme services for each of the thirteen larger countries; European Russia being regarded as two countries as it has two main languages. For the seventeen smaller countries the size of which does not require the use of long waves to secure effective coverage, the national programmes are allocated to some, but not the whole, of the band between 552 kc./s. and 1,157 kc./s. (260–544 m.). The remainder of the medium wave-band, up to 1,553 kc./s. (193 m.), with one or two exceptions, and the portions of the above band not used for national services, are to be divided up for regional purposes, common-wave working being envisaged for stations separated by a distance of at least 1,500 miles. The scheme suggests provision for eleven regional transmitters in Great Britain and Northern Ireland in addition to two national transmitters working on 178 kc./s. (1,685 m.) and 222 kc./s. (1,350 m.).

In brief, the proposed plan claims to give the following facilities: two adequate national channels for every country; an increase in the frequency separation from 9 kc./s. to 11 kc./s., resulting in a material decrease in interference; and a better regional service even in England, and vastly better for the majority of Europe. If the complete scheme is to be satisfactory, however, it is emphasized that it is essential to have better control and regulation of the power, frequency and modulation of broadcasting transmitters all over Europe than has been the case in the past.

In presenting the report summarized above, the Radio Industry Council makes it clear that its proposed solution of the problem is by no means rigid or final, since considerable elasticity is offered in the exact wave-length allocations without affecting the general scheme. It is, however, commended to the earnest consideration of those who are able to influence the future development of broadcasting, in the belief that the present phase in Europe presents a valuable opportunity and, in the view of the British radio engineers represented by the above Council, an obligation to correct past mistakes.

SYNTHETIC RUBBER FROM ALCOHOL

Synthetic Rubber from Alcohol

A Survey Based on the Russian Literature. By Anselm Talalay and Michael Magat. Pp. xiii+298. (New York: Interscience Publishers, Inc., 1945.) 5 dollars.

THIS book is well written and printed, free from typographical mistakes, and generally very readable. It is divided into four chapters. The first chapter deals with the chemistry of the Lebedev process for preparing butadiene from alcohol, the second with the technology of the process, the third with the fundamentals of polymerization, including a sub-section on the technology of sodium polymerization, and the fourth with the physico-chemical properties of the polymer, including a most important section on determining the structure of the polymer. While the book as a whole was a co-operative effort of both authors, Chapters 1 and 2 were mainly the responsibility of A. Talalay and Chapters 3 and 4 of M. Magat. It is to be regretted that a further chapter dealing with Russian experience in handling polybutadiene in the rubber factory was not added. Useful author and subject indexes are appended.

The writing of the book is justified by the fact that so few English-speaking technical men can read Russian. A survey must always suffer from lack of authoritative information, and this book is no exception. While the authors have done a good piece of work in bringing together so much valuable information locked away in journals difficult to obtain and more difficult to translate, the reader has the impression that the authors are no better informed on what real progress has been made in the development of synthetic rubber in the U.S.S.R. than he is himself.

This doubt arising from the reviewing of the work of others is quite frankly expressed in the text by the use of the word 'apparently'. This is really a great virtue on the part of the authors, since less honest writers might have been tempted to identify their own views with those of the original authorities.

It is also regrettable that Russian references to more recent work (most of the references are more than ten years old) are not very numerous.

Attention should be directed to the statement on p. 145: "the Germans soon abandoned this method of polymerisation" [sodium polymerization]. This is, of course, untrue since the Germans only abandoned it for the production of products which could be made more efficiently by the dispersion technique. Conversely, more attention could have been paid to the reasons why emulsion polymerization offered difficulties in the case of straight butadiene polymerization.

The practical side of the book (that is, the technology of production) deals almost exclusively with the production of butadiene and polybutadiene. This, naturally, is to be expected from the second part of the title of the book. The reviewer is somewhat surprised that the authors have not mentioned in their introduction Smirnov's book, which covers largely the same ground, at least from the technological angle. It is also rather to be regretted that the title (save for the second conditional part) and contents may lead beginners in the field to the wrong conclusion that polybutadiene is the most important rubber produced from alcohol. Buna *S* (or its analogues) is, of course, the most important synthetic rubber produced from alcohol in the past and present, although there are some indications that polybutadiene may be the most important in the future. This possible misunderstanding might have been avoided by employing a more limited title such as "Polybutadiene Rubber from Alcohol". The authors have, indeed, pointed out that the co-polymers with styrene and acrylonitrile are important, but, in the view of the reviewer, with insufficient emphasis. It is true that some specific information regarding the American processes is still restricted, but no one could deny that far more has been published regarding the general position of synthetic rubber development in the United States than in the U.S.S.R.

A considerable amount of the material contained in the theoretical sections of the book is derived from non-Russian sources, and this makes it even more regrettable that more attention was not given to the production of Buna types from alcohol in the early technological sections of the book. A correspondingly large proportion of non-Russian references in the early part of the book would have made this possible.

The book is essentially one for the chemist interested in the development of synthetic rubber. It is feared that the average rubber technologist will find the treatment of the subject too academic. On the whole it is a book to be recommended.

W. J. S. NAUNTON.

PRACTICE AND SCIENCE IN THE SHEEP INDUSTRY

(1) The Merino

Past, Present and Probable. By H. B. Austin. Second edition. Pp. 247. (Sydney: Grahame Book Co., 1944.) n.p.

(2) Sheep

By J. F. H. Thomas. With Chapters by Moses Griffiths, Martin Jones and A. R. Wannop. Pp. 196+44 plates. (London: Faber and Faber, Ltd., 1945.) 15*s.* net.

"THE sheep has golden hooves, and wherever the print of them appears, the soil turns to gold." This old Swedish proverb is quoted by Mr. Austin; Mr. Thomas could equally well have taken it for one of his texts. The former is concerned with the role of the Australian Merino stud sheep in leading commercial wool production; the latter covers the great complexities of breeds, crosses, methods of management, and diseases which are compounded in the sheepbreeding industry of Great Britain.

Both authors are practical men who have earnestly set out to assess the contributions that science has made, makes, and could make towards technical progress in matters of sheep-breeding and husbandry. Both are optimistic regarding the future of the sheep industry, with important reservations as to policies and methods. Both are quite ready to enliven their matter by interjecting subjective views, criticisms and personal opinions. While each has written primarily for practical men specially interested in the industry of their own country, the scientific reader can be advised to regard the books as complementary, to forgo criticisms of many of the obvious weaknesses and deficiencies, to accept the sincerity of the authors' arguments, and to appreciate the valuable contributions each makes to the literature of the livestock industries.

(1) Breed history is a proper background for the study of breeding methods, and Mr. Austin has performed a remarkable service in amassing so much in the way of contemporary records, opinions and data on those strains of sheep which have gone to make the modern Australian Merino. His main interest is focused upon the history of the important strain of Peppin Merinos, so that his history does not cover all, or even most, of the other varieties or sub-breeds of Merino. In this sense the book appears somewhat unbalanced, but it would have been an excessively formidable task to give such a history of all Merino strains. However, it is certainly safe to say that this account can never be neglected by anyone wishing to learn the story of any kind of Merino. Apart from the quotations from the literature, the author's analyses of the trends and dictates of fashion or whim in changing breed type and form are of special interest and fascination, enhanced in value by the remarkable collection of illustrations showing the different stud types favoured in the various eras of Merino breeding.

The fashion in one era is fiercely attacked. The disastrous craze for the "heavily wrinkled horrors" of the Vermont type which pervaded much of Australian Merino breeding for about thirty years from 1890—although it had previously begun to ebb in the American home of this strain—had seriously disturbed the steady development of the plain-bodied Merino sheep yielding a sound and fairly uniform fleece of good commercial wool. Though this craze has now passed and been replaced by more sensible breeding aims, Mr. Austin claims, with good evidence, that the mating and selection methods introduced and publicized by the Vermont enthusiasts have left an unfortunate legacy of belief in the value of "corrective matings". He argues convincingly that there has been no great genetic improvement in the Australian Merino, that there is an urgent need for the establishment and wide use of objective tests of wool-producing ability, and that a near-worship of pedigree must be replaced by a realistic and thorough application of performance and progeny tests.

In support and elaboration of this last argument, and in his hearty enthusiasm for applied genetics, Mr. Austin devotes four of his thirteen chapters to a discussion of the principles of genetics and their application to Merino breeding. He has made a serious attempt to understand some of the recent advances in this branch of biological science, but unfortunately he appears to have gained more respect than true understanding or discrimination Unfortunately, because while the geneticist will not be misled by his discussion, or by the illustrations and diagrams from well-known text-books here reproduced as hallmarks to the accompanying matter, the layman might. Yet, in spite of this danger that the book might be accepted by some breeders as an authoritative statement of genetical fact and theory, it is significant and symptomatic that so much of the genetical approach should be included and presented as a practical means towards the future development of this important breeding industry.

(2) Mr. Thomas, on the other hand, gives us only an account of the actual application of progressive methods in everyday sheep husbandry in Great Britain, and incidentally shows forcibly at times how the scientific worker has neglected some important phases of the farmers' problems. His book is "an attempt to give a picture of the sheep and sheep farming of Great Britain at the present time". While his three collaborators deal with the special regional aspects of sheep farming in Wales, in the mountains and hills of Scotland, and in the Scottish Border counties, he covers the wider field in a practical, and often provocative, manner. Mr. Thomas is happiest when dealing with the methods and complexities of the industry at large as judged against the background of an intimate knowledge of management under that most intricate system of sheep husbandry, the arable flock. The all-too-short outline of his own practices is a highly valuable contribution. When, however, he sets out to deal with specific technical subjects, as in Chapter 5, "Flock Hygiene: Diseases and Other Causes of Loss", he is not so happy and his presentation will appear weak to the specialist. Yet even in this chapter his concluding paragraph shows his whole attitude directly and convincingly: "From this long and depressing catalogue of the ills to which sheep are subject, one salient fact emerges—many of the causes of loss in sheep are directly due to man's ineptitude. Good management and good shepherding result in healthy flocks, a minimum of loss, contented sheep, and less harassed flock-owners".

Sheep and sheep-farming methods are not the exclusive theme; the picture given of the industry is that of only a part of British agriculture. The author believes, deeply and strongly, in livestock as a most potent factor in the general agricultural situation of Great Britain. He argues for an expansionist policy for agricultural production, in which he sets as a reasonable target 31,000,000 sheep in 1949, some six million more than we had in England, Scotland and Wales in 1939. For the development of the sheep industry he requires firm governmental action and a progressive agricultural policy, with stabilized prices, guaranteed markets, and organized marketing as "obvious essentials". Intensified and extended research and technical education are also needed. But this is not all; there is the other side, on which the sheep farmer must "accept responsibility by striving in every way to improve his methods of breeding and management". Mr. Thomas means, and plainly reasons in this stimulating book, that "the future of our sheep industry depends upon the team-work of the State, the flock-owner, and the shepherd".

J. E. Nichols.

A PLAN FOR DECENTRALIZING ADMINISTRATION IN GERMANY

The Regions of Germany

By Dr. Robert E. Dickinson. (International Library of Sociology and Social Reconstruction.) Pp. ix+175. (London: Kegan Paul and Co., Ltd., 1945.) 10*s.* 6*d.* net.

HAVING in mind the need to curb the aggressive strength of a united, highly centralized Germany, the author claims for his regional scheme the means of preventing the continued domination of the country by Prussia. His advocacy of a partition of Germany into autonomous or semi-autonomous areas leaves doubt, unfortunately, as to whether a federated or a confederated Germany is recommended, and there is vagueness as to the extent of devolution proposed. Indeed, the proposed relationships of the individual regions with the central government and with each other are scarcely, if at all, discussed, despite their importance to the statesman and administrator, for whom presumably the book is primarily intended; while, in view of the author's fear of Prussian hegemony, we should expect an alternative to Berlin to be proposed as the supreme headquarters of government.

Economic geography provides the principal criteria for the author's system of regions. Social considerations, by contrast, are granted negligible importance. Moreover, the emphasis laid on partition tends to obscure the closeness of the economic and social associations which draw the provinces of Germany together, and if the advice offered were to be followed it might well result in the 'balkanization' of Central Europe. The experience of the Soviet Union, which may usefully be cited on this point, is that nations (for example, the Ukrainian and the Belorussian) are stoutly opposed to the subdivision of their territories into 'economic regions' for purposes of convenience in administration. In the same way, a too-ruthless departure from the boundaries of traditional units is not likely to gain the willing sanction of the German people.

Although it cannot be conceded that the author's purpose is fulfilled—and considerable ambiguity does not help the reader—this essay on the economic geography of Germany should prove useful to students, especially those without direct access to the work of the German regional geographers, whose authority Dr. Dickinson freely acknowledges. The confidence of the reader would be increased by the careful revision of inaccurate or loosely worded statements, only one or two of which are here indicated. The geographical interpretation in the text of the population density map (p. 37) is not borne out by the evidence which the map itself provides. The two 'belts' of high density to which particular reference is made are by no means obvious, even if due allowance is made for generalization. Admitted that geography suffers from a paucity of technical terms, it should nevertheless be possible to avoid such a statement as (p. 70) "The belt has about 3½ million inhabitants. . . . It falls into 3 belts". The suggestion that the aggressions and barbarities of German policy are attributable to a wicked Prussia which, by its domination, has prevented the development and expression of the latent democracy of non-Prussian Germany, is confuted by the history of the totalitarian Nazi creed, in which the part played by Bavaria does not seem to have been inconsiderable.

W. FITZGERALD.

THE BLACK WIDOW SPIDER

Black Widow

America's Most Poisonous Spider. By Raymond W. Thorp and Weldon D. Woodson. Pp. xi+222+16 plates. (Chapel Hill, N.C.: University of North Carolina Press; London: Oxford University Press, 1945.) 18*s.* 6*d.* net.

THE 'black widow' has for long been the popular name of the American spider *Latrodectus mactans*, notorious above all others for the reputed virulence of its bite. In 1934 there was a remarkable increase in the numbers of the species, and the recorded cases of spider-bite, or arachnidism, so alarmingly multiplied that the 'black widow' acquired a 'news value' in the popular Press. Messrs. Thorp and Woodson then undertook a comprehensive study of this spider, the results of which are contained in this book.

It opens with a somewhat irrelevant account of spider myth and legend, including such extremes as the words of the Koran and the story of Little Miss Muffet, followed by a most interesting chapter on the Tarantula and a very incomplete survey of other poisonous spiders. Thereafter the book deals only with *Latrodectus mactans* and other species of the genus which occur in other parts of the world.

An admirable historical account of medical experience occupies eight chapters. After the earliest recorded spider-bite in America, on September 3, 1726, the first extensive collection of cases was published in 1901 by Dr. C. C. Browning. A quarter of a century later, Dr. Emil Bogen of Los Angeles produced the first of his well-known papers on arachnidism, establishing it as a clinical entity and reviewing all available information. Dr. Bogen, who has continued this work, contributes a foreword to this book, and is acknowledged by its authors to have been most helpfully associated with their studies. There are now records of 1,291 cases, involving 55 deaths. Thus it is fair to say that arachnidism, like hydrophobia and the rattlesnake bite, causes a few deaths each year; but it is essentially avoidable and is surprisingly infrequent in view of the wide dispersal of the spider. We are told that by far the commonest cases are those in which the spider's web has been spun beneath a lavatory seat and the patient has been bitten in the genitalia; that the poison spreads with extreme rapidity; that it particularly affects the nerves; and that the very severe pain is felt throughout the body; that wrong diagnosis is frequent; and that more than ninety different remedies or treatments have been recommended.

The latter half of the book is less scientific. It includes a review of the public interest in the spider, which mentions several trivialities, an elementary account of the class Arachnida and a popularly written description of the habits of the 'black widow', in captivity and elsewhere, as observed by the authors. There is also a survey of the distribution of the spider, which resists equally the cold of Denver and the heat of California, the drought of Yakima Valley and the moisture of Alabama, and has been found from sea-level to an altitude of 8,000 ft.

Some rather inconclusive suggestions for natural and artificial control of the 'black widow' bring to an end an interesting and generally successful example of popular treatment of a scientific subject.

T. H. SAVORY.

SCIENCE IN THE U.S.S.R.*

EVOLUTIONARY BIOLOGY AND RELATED SUBJECTS

By Dr. JULIAN HUXLEY, F.R.S.

IN the U.S.S.R., a convergent attack on the evolution problem is being made from many angles simultaneously—from that of genetics, of taxonomy, of ecology, of cytology, of field studies and behaviour, of mathematical analysis, of comparative anatomy, of palæontology. In this, the U.S.S.R. resembles Britain, the United States and other countries, though it is interesting to find that during the War a good deal of the work has been carried on independently, in total or partial ignorance of research elsewhere. The approach has in general been along the same neo-Darwinian lines, involving acceptance of neo-Mendelism, as in Britain and the United States, though perhaps with even greater emphasis on strict selectionist principles. This is all the more interesting, since in the U.S.S.R. neo-Darwinism is in sharp contrast with the revolutionary views of the botanist and agriculturist Lysenko. Lysenko's conclusions and theories demand an article to themselves. Here we can only say that though Lysenko claims to be a true Darwinian, his contentions involve a sweeping form of Lamarckian inheritance, as well as remarkable effects of scion on stock in grafting, and their hereditary transmission. Further, he expressly states his disbelief in Mendelism or any other particulate principle of heredity. Lysenko is in a powerful position, both scientifically, as president of the Lenin All Union Academy of Agricultural Sciences, and politically, as vice-chairman of the Supreme Soviet. However, in spite of this, the neo-Mendelian and neo-Darwinian selectionists continue to turn out large quantities of excellent work (thus disproving the contention sometimes advanced by non-Russian men of science, that scientific theory in the U.S.S.R. is always subject to political considerations). Indeed, in Lysenko's own Institute are to be found research workers on *Drosophila* genetics and cytology, and a former member of the staff of Vavilov, the eminent plant geneticist (now dead), who was Lysenko's most prominent antagonist before the War.

In what follows, I propose to mention some of the work in the more important fields of research which I came across during our two weeks in the U.S.S.R., in the hope that this will facilitate that renewal of contacts which is so desirable after the isolation caused by the War.

Work on *Drosophila* is in progress in numerous institutions. In Dubinin's Laboratory of Genetics in the Institute of Cytology (Moscow), Dubinin himself is studying the selective effects of various inversions in natural populations. One inversion has a selective advantage over the normal at low temperatures. Several others are at a *disadvantage* at low temperatures, and are much more numerous in urban conditions: the result is to produce a balanced polymorphism as between urban and rural populations, similar to that found with industrial melanism in moths, though the selective agencies are quite different. Berg and Dubinin have also found a seasonal balance as regards the mutant wing-vein character *extra-analis*. All the polygenes responsible for this character are in one chromosome, a state of affairs which Dubinin maintains must be due to selection. Dubinin has also some very interesting work on mutation-rate—its general control by selection; the existence of strains highly mutable for yellow; etc.

In conversation, Dubinin recalled the fact that in 1931 he (with Romashov), had, simultaneously with Sewall Wright but quite independently, enunciated the principle of non-adaptive evolution in small populations. (Unfortunately, he used the cumbersome phrase 'genetical-automatic processes', and the convenient American term 'drift' has quite superseded this.) Siderov is studying the position-effect with regard to yellow. The frequency of yellow mosaics is related to contiguity of the yellow locus to the 'inert' region of the chromosome; it is also related to development—thus the manifestation of yellow-mosaicism is less frequent on the head than on the body. Other problems of physiological genetics will be investigated by Rappaport on his return from service.

Work on mutation is also being carried on by Shapiro in Academician Serebrovsky's Department of Genetics in the University of Moscow (though mainly on a new genetic object, the melichid fly *Dermmetopa*); by Olenov in the Genetics Department of the Roentgen Institute in Leningrad; and by Miss Berg in Schmalhausen's laboratory in Moscow. Berg is also doing interesting work on natural populations, especially on the evolution of dominance, and on the effects on different mutants of the varying types and intensities of selection which prevail at different periods of the annual cycle.

In Academician Lysenko's Institute of Genetics, apart from Lysenko's own work (with Glushchenko and others) on grafting and the inheritance of its effects, which I do not propose to discuss here, Prokofieva is making an extremely interesting study, from the cytological aspect, of the metabolic cycle of chromosomes (which she has christened 'heterocyclicity'), notably in regard to the difference between the paternal and maternal genomes. Nujdin is working on *Drosophila* here, and on his return from military service, Belgovsky will continue his work on the pure genetics of *Drosophila*.

In mathematical genetics and evolution theory, important work is being done by Kolmogorov, Malinovski, Smirnov, Ignatiev, Romashov, Schmalhausen and others. Schmalhausen is working on what he calls 'stabilizing selection' and the different reaction-norms to be expected in different types of environment.

It was of great interest to find that the Pavlov Institute at Koltushi (Leningrad) has a department devoted to the genetics of behaviour. Here, Dr. Masing is studying the inheritance of phototaxis in *Drosophila*, and has also obtained valuable results on the genetic basis of egg-laying preferences, which help to explain the origin of 'biological races' and monophagous species. Meanwhile, Promptov is studying the effects of environment and of heredity on activity and other aspects of behaviour in finches. This, I believe, is the only work that has been done on the genetics of behaviour in wild bird species. The study of the inheritance of temperamental types in dogs, begun under Pavlov, will be continued, and is to be extended by similar work on pure breeds, the material so far having been genetically quite heterogeneous.

In the Institute of Cytology, Sacharov, using colchicine, has produced a valuable new tetraploid form of buckwheat. He has also found that in an artificial poppy tetraploid, the tapetal cells of the anthers remain octoploid, as in the normal diploid—an interesting example of regulation. Frolova, as well as studying the cytology of these tetraploids, is doing work on the digestion of different parts of chromosomes by different enzymes and other agencies, which should be of general importance. Peshkov has obtained what appears to be conclusive evidence of chromosomes and their division in a bacterium (a giant form, *Karyophanon*), and is also studying the peculiar endomitosis of *Chara*. In Navashin's laboratory in the same Institute, a giant and highly fecund tetraploid of a valuable rubber-producing composite has been artificially produced. Navashin himself is now studying the dynamics of mitosis in *Crepis*.

---

* Continued from p. 228.

In the Institute's Laboratory of Experimental Embryology (besides interesting work on morphogenesis which cannot be discussed here) Astaurov, working on silkworms, has obtained both parthenogenetic males and females. Schmidt is continuing his well-known researches on the nemertine *Lineus*, which showed the existence of two modes of development, one where the eggs are larger and all develop, producing Desor larvæ and green adults, and the other where the majority degenerate after early segmentation, and are ingested by the remainder, which develop into large-mouthed larvæ and red adults. He now considers these as separate but close species, differentiated after genetic isolation. In the red species (*L. ruber*), he now finds that the percentage of degenerating eggs is the same (87 per cent) in two widely separated subspecies with slightly different-sized eggs and markedly different egg-totals. He suggests that this depends on a genetic mechanism involving balanced lethals—if so, a remarkable case of lethals being utilized to produce an adaptive result.

'Close species' in plants and other botanical species-problems are being studied by Rosanova in the University Genetics Laboratory. Here also, Khostova has been independently repeating some of Lysenko's work on the effects of grafting on tomatoes, I understand, with largely negative results; Alikhanyan is studying structural mutations; and the director, Serebrovsky, has been working on the genetics of parasitoids for practical purposes. Among other results he has obtained a wingless strain of *Sitotroga* to serve as food (host) for the useful *Trichogramma*; this is of importance as reducing the danger of spread of *Sitotroga*, which is a pest.

In Schmalhausen's laboratory, Mashkovtsev and his colleagues are doing a good deal to generalize the modern thesis that courtship and display (and other external stimuli connected with the breeding habitat) have a physiological effect in ripening the female gonads in birds and mammals.

Very interesting work is being done by C. F. Gause. Employing ciliates, he has given the first experimental proof of the efficacy of organic selection. He finds that both salinity and temperature changes normally induce modifications in body-size; when conjugation is induced, segregants appear with a large range of body-size, but only those survive which are of the same type as the modifications. Gause is now devoting himself mainly to medical research on gramicidin, but hopes to give some of his time to evolutionary studies.

Alpatov has shown that the correlation which he had previously established between tongue-length and latitude in bees is found only in the workers, not in queens or drones, and is thus presumably an adaptation to the flowers visited. He proposes to extend this work to bumblebees. He has also established the important fact that the irreversibility of the transformation of the head-louse to the body-louse is a selection effect. The head-louse shows a great range of variability; in the five or six generations required to transform it into the body-louse, heavy mortality occurs and the variability is reduced, so that the reverse process is impossible. The body-louse is thus a specialized type, produced by a selection which Alpatov considers is mainly one for tolerance of lower temperature.

Work on the genetics of cancer is being done in the Genetics Department of the Oncological Institute in Moscow under Martinova, and on the genetics of coarse fish by Romashov in the Genetics Department of the Freshwater (Pond) Fish Institution in Moscow. I was informed that information on the genetics of fur-bearing animals and on their variation and polymorphism in Nature was to be obtained from the Central Fur Laboratory of the People's Commissariat for Foreign Trade (Profs. Petrayev and Manteufel), but was unable to make contact with them.

In taxonomy, excellent work is being done, both in the University Museum of Zoology, Moscow, and in the large Museum of Zoology in Leningrad (famous for its specimens of mammoth and woolly rhinoceros with skin and hair), to which is attached the Zoological Institute of the Academy.

In Moscow, Dementiev told me that he had been so stimulated by the publication of the "Handbook of British Birds" during the War, that he and a team of collaborators are now preparing a handbook of the birds of the U.S.S.R., which will aim at very full ecological treatment. This will be a formidable task, as there are 675 species to cover; but it will be of the greatest value to ornithology and to taxonomy in general. Heptner, the mammalogist here, is pursuing zoogeographical studies, as is Turov. Heptner is also working on polymorphism in *Mustela*, *Myospalax*, *Arvicola*, etc. The marten (*Martes martes*) and the sable (*M. zibellinus*) show a 'hybrid zone' very similar to that between the carrion and hoodie crows. There is also a chair of zoogeography in the University of Moscow, held by Bobrinskoi, who has just published a book on the mammals of the U.S.S.R., while Puzanov of the University of Gorki has published a text-book of zoogeography. Lukin, professor of biology at the University of Kharkov, is also working on biogeography and has published a book on Darwinism and the geographical variation of organisms.

In Leningrad, much work is being done on the taxonomy of the various main groups of animals, and numerous books are being published, including many volumes of the detailed Fauna of the U.S.S.R. (chiefly anatomical and systematic). At the Leningrad Museum an interesting feature (unfortunately rare in Britain) was the linking of museum systematics with physiology and ecology. Thus the entomologist Kushentsov is writing a book on the comparative physiology of insects, and Rubtzov works chiefly on the ecology of Diptera. The curator of mammals, Vinogradov, is also professor of vertebrate systematics and ecology in the University of Leningrad, and maintains a field station for his students. In the University Department of Entomology, Shvanvich has perfected a new method for demonstrating the true value of 'ruptive' coloration in Lepidoptera, in breaking up the flat plane of the wings into a number of apparently different levels: in some cases the result simulates a foreground of grass stems against a dark background. He has also made a valuable study of the evolution of wing pattern within single families—a veritable comparative anatomy of pattern and its elements.

To return to ecology, the leading animal ecologist in the U.S.S.R. is Formosov. Unfortunately, he and his staff were away in the field at the time of our visit, so that I had no opportunity of hearing of their current researches, nor did I make contact with Sinskaya or other plant ecologists. Attached to the Zoological Gardens in Moscow is a small but interesting institute, the Laboratory of Experimental Ecology, under Kalabukhov. He and his assistant Afonska are making quantitative studies of the activity, temperature preferences, respiration, and oxygen consumption of various mammals—bears, foxes, field mice, hamsters, martens, etc.—and finding adaptive correlations with local environmental conditions. Work is also being done on the change of colour to winter white in *Cricetulus* and *Lepus*.

At the Museum Darwinianum in Moscow, in addition to the remarkable exhibition methods (which include a large number of striking paintings and sculptures by the artist Vatagin), Kohts, the director, has an extraordinary collection of aberrations in various species of birds and mammals. The most interesting are in blackcock, where more than 200 million specimens from the markets for some four hundred years had been gone through! As a result, Kohts is able to say that a dilute ('blue') form occurs once in about 2½ million specimens, a form with checked black-and-white belly once in 10 million, and so on. Mme. Kohts is continuing her work on the behaviour of chimpanzees (a subject which is also being studied, with interesting results, at the Pavlov Institute at Koltushi).

Boris Zavadovsky also has a Museum of Evolution in Moscow, but this is more popular and takes in more general biology. It comprises a number of living exhibits. Zavadovsky writes a good deal on theoretical biology and on Marxism in biology, as well as doing practical work on artificial insemination, on pregnancy tests, and tests for the sex of unborn mammalian offspring.

In general, much less research is being carried on in university departments than in the special institutes of the Academy of Sciences and other non-university institutions. However, the disparity does not seem to be so great in biology as in the physical sciences. Genetics is at present taught only in the University of Moscow: specially able students from other universities may be sent to Moscow to take this course. Genetics is studied during the last two and a half years of the five-year undergraduate course in biology; there are now about twenty genetics specialists. During their final year, students are encouraged to do small pieces of research under guidance. The courses in plant and animal genetics are different, but all genetics students do some work with *Drosophila*, as well as cytology, biometry and phenogenetics.

As we only had a short time in the U.S.S.R. and did not visit many cities, the above account of work in progress is very incomplete (though it appears that a large percentage of the more important research is concentrated in Moscow and Leningrad). Thus I was unable to see anything of the work in agricultural genetics, notably the genetical research being carried on in the huge agricultural institution, the Timiriazev Academy near Moscow (where I understand much valuable work on polyploidy and on the genetics of cereals is in progress under Academician Jebrak); nor could I see that in the equally huge Forestry Research Institute near Leningrad, or the work on polyploidy in Breslavetz's department at the Botanical Garden of the University of Moscow. Karpechenko, the well-known plant geneticist, is unfortunately missing, presumed dead.

I had not the time to discover what had happened to the remarkable programme of work on the evolution and genetics of crop plants initiated by Vavilov (except that some of the seed-collections left at Leningrad were eaten during the siege). The abundant and valuable work in palæontology is being described by Prof. D. M. S. Watson and Dr. Edwards. Here I will only record the excitement of seeing a fossil Paleoniscoid fish larva from the Jurassic, with eyes and yolk-sac beautifully preserved.

In general, I may sum up my impressions as follows. In spite of the insistence during the last four years that Russian biologists, like other men of science in the U.S.S.R., should do some work of importance for the war effort, pure research seems to have been kept going to a somewhat greater extent than in Britain during the War (and, according to some of the American delegation, than in the United States.)

In some branches of Russian science, a certain spirit of scientific nationalism is to be observed. There is little of this, however, in general biology, apart from the efforts made in certain quarters to elevate Michurin from the position of an agricultural and horticultural empiricist to that of a great scientific pioneer and discoverer (there is even a town which has been re-christened Michurinsk, where much of Lysenko's work is now being carried on).

If in the U.S.S.R. no outstanding discoveries appear to have been made, no new principles established, in the field of general biology during the last few years (again I defer any discussion of Lysenko's work until later), yet the work has been of high quality, many-sided in its approach, and of great volume (though not so voluminous as, for example, in geology or agriculture).

In spite of the War, my Russian colleagues seem to have managed to obtain rather more knowledge of British and American results than we did of their work, though their supply of foreign and scientific books and especially journals is still very inadequate. They all showed the greatest courtesy and friendliness and were anxious to tell us of all they had been doing and thinking. They are hoping for a rapid improvement in the facilities for interchange of personnel, as well as of reprints, journals and books.

The U.S.S.R. is taking its place as one of the foremost countries in biological research, and I anticipate that they will soon be leading the world in some fields, notably in the relation between ecology, field study, taxonomy, genetics and evolution, where their vast continuous territory, with its extremes of environmental conditions, provides them with unrivalled opportunities.

CRYSTALLOGRAPHY

By Dr. W. A. WOOSTER
Department of Mineralogy and Petrology, Cambridge

ONE of the evil effects of the War has been the virtual isolation of scientific workers from their colleagues in foreign countries, and it was a particularly welcome invitation which the Russian Government extended to British crystallographers. During the War the laboratories in Moscow and Leningrad were largely evacuated to Kazan and other places in the east, and the resettling process is not yet complete. In spite of these difficulties, much fundamental and applied work has been carried on during the whole of the war period. The laboratories under the Academy of Sciences are well equipped with apparatus and have many trained scientific workers on their staffs.

The laboratory for morphological crystallography is in the Crystallographic Institute in Moscow. Part of the work of this laboratory consists in the routine examination of crystals derived from the numerous mineral deposits of the U.S.S.R. X-ray crystallography is carried on in at least four departments in Moscow. The substances studied in the Institute of Crystallography and in the Karpov Institute for Physical Chemistry are mostly minerals or inorganic substances. Among the former is included dioptase, the structure of which has recently been worked out, and among the latter, a number of cyanides, ferrocyanides and compounds containing other complex ions (Belov, Zdanov, Boky, Popova). Electron diffraction apparatus is being used for the study of crystals which occur in very thin flakes, for example, cadmium iodide and clay-forming minerals (Pinsker). Work, both theoretical and experimental, on certain inter-metallic phases and on the structure of thin metallic films is being carried on in the Physical Institute of the University under Prof. Konobievsky. The study of the influence of the state of chemical combination on the X-ray absorption edges and on the emission lines of certain elements is conducted by Prof. Borovsky in the Department of Petrology.

Crystal physics is much studied in the U.S.S.R. The school established more than twenty years ago by Academician A. Joffe has pursued its study of the properties of crystal and other solids with undiminished vigour. The work of Mrs. Joffe and other members of the Physical-Technical Institute in Leningrad, under the direction of Joffe, has shown the existence of new types of semi-conductors. A systematic survey of oxides and sulphides, particularly those of titanium (TiO_2), copper (Cu_2O), vanadium (V_2O_5), tungsten (WO_3), lead (PbS) and tantalum (Tl_2S), has shown that much more efficient rectifiers and photo-cells can be made with new combinations of metals and semi-conductors than can be obtained from the usual selenium-iron combination. The current per unit light intensity obtained with a tantalum sulphide – iron combination is twenty-five times greater than that given by the selenium – iron combination. Such photo-cells have now become sufficiently efficient to make it practicable to set up large batteries of them in desert places for the conversion of solar radiation into electrical energy.

It has also been shown that lead sulphide may give electronic or hole-conduction according as there is an excess or a defect of lead in the crystal structure, and that conductivities up to a thousand times that of the pure substance may be obtained with the material containing non-stoichiometric proportions of lead and sulphur. Work on these semi-conductors may have far-reaching effects on the manufacture of photo-cells and dry rectifiers.

Prof. Schubnikov (Institute of Crystallography, Moscow) has developed a new field by the study of piezo-electric textures. A cloth or wire gauze is stretched on a frame and molten Rochelle salt is brushed on, the direction of movement of the brush being always the same. In this way a plate looking rather like a plaster plate is built up in which the needle-shaped crystals of the salt are preferentially orientated in the direction of movement of the brush. Such a plate when coated with tinfoil or other electrodes forms a piezo-electric element suitable for the acoustic range of frequencies. Its internal damping is too high for it to be used in the supersonic range, but it can be used satisfactorily for microphones. Such plates may be made with the preferential orientation in one direction only or in two directions according to whether the plate is to be used for bending or twisting. These plates are strong and can be made of almost any size. Prof. Schubnikov has given the necessary extension of the theory of piezo-electricity to cover these preferentially orientated textures. Methods have also been found in the same laboratory of growing large single crystals of substances suitable for piezo-electric apparatus, for example, Rochelle salt, potassium dihydrogen phosphate and cane sugar. In relation to the latter crystal, it has been shown (Scheftal, 1941) that a change in the degree of supersaturation from 2·4 to 2·1 per cent makes all the difference between the development of a bad or a good crystal.

The mechanical properties of crystals have been studied intensively in the U.S.S.R. in recent years. A number of investigations by Miss Classen-Nekludova have demonstrated many of the fundamental facts concerning the plastic deformation and the rupture of rock-salt and certain metallic crystals. She has shown that rock-salt, when subjected to intense compression in one direction at a high temperature, twins according to a spinel law. Further studies on artificial corundum have shown how to determine the orientation of the crystallographic axes by optical means, what strains are present in the boules and how these strains influence the breakage of the specimens. A novel development in the study of the plastic properties of metals has been introduced by Stepanow (Physical Technical Institute, Leningrad), who uses fused silver chloride as a 'transparent metal'. The elastic and plastic properties of this substance have been shown to be of the same type as those of a metal. It shows a photo-elastic effect in polarized light, and this opens up possibilities of new studies on the plasticity of metals. A special plastic called 'Escapon' has been developed during the War, and it has excellent electrical and mechanical characteristics. It is made from butadiene rubber by compression at 20–50 atmospheres and between 16° C. and 200° C. according to the hardness required in the final product. A development which Joffe described as the 'vulcanization' of cellulose consists in acting on cellulose with certain quaternary ammonium bases to form oxygen bridges between the cellulose chains. Filter paper subjected to the action of these bases is rendered incapable of disintegration by water and it retains its strength even when immersed in hot water.

The following text-books in Russian have appeared recently: "The Elements of Crystallography", by A. V. Schubnikov, E. E. Flint and G. B. Boky (1940); "Elementary X-Ray Structure Analysis", by G. S. Zdanov (1940); "X-Ray Analysis of Metals", by G. S. Zdanov and Y. S. Umansky (1941); "Symmetry", by A. V. Schubnikov (1940); "Quartz and its Applications", by A. V. Schubnikov (1940); "New Apparatus for Crystal-Optical and Petrographic Investigations", by the staff of the Institute of Crystallography, Moscow (1940); "Crystals", by M. Shaskolskaya (1944); and "Analysis of Crystals by their Optical Properties, Part I", by G. B. Boky (1944).

In conclusion, it may justly be said that the study of the properties of crystals is in a very flourishing state in the U.S.S.R. at the present time, and it is to be hoped that the move towards co-operation so generously started by the Soviet Government will be reciprocated in the coming years.

PEDOLOGY

By Dr. ALEX MUIR

Rothamsted Experimental Station

THE development of pedology or soil science owes much to the initiative of Russian men of science, foremost among whom was V. V. Dokuchaiev, who laid the foundation of modern methods of soil classification. It is appropriate, therefore, that the principal centre of soil study in the U.S.S.R., the Dokuchaiev Soil Institute of the Academy of Sciences, founded twenty years ago, should bear his name. Many well-known figures in soil science have been associated with this Institute—Glinka, Gedroiz, Neustruev, Lebedev—and the British soil workers attending the recent Academy celebrations have had close contacts with the Institute since its foundation. We were given a great welcome on our arrival, and made honorary members of the staff for the duration of our stay so that we could come and go as we pleased. The present director, Academician L. I. Prasolov, and his staff had made careful preparations for the visit, and all the accounts of work in progress were fully illustrated with maps, diagrams and apparatus.

The activities of the Institute include research work on theoretical problems of soil science such as the genesis, geography and cartography of soils, soil systematics and classification, soil chemistry, physical chemistry, biochemistry and physics; but the practical side is not forgotten, and there are departments of agrochemistry and soil erosion, while saline soils and their utilization receive considerable attention.

Prasolov, who recently celebrated his seventieth birthday and forty years of scientific activity, is ably assisted by some 116 scientific and technical workers. A number of the senior members hold chairs in other institutions, which ensures close collaboration between the different organizations. In addition to this overlapping of staff, the Dokuchaiev Institute has a number of affiliated institutes in the various republics and some out-stations for the study of soils *in situ*.

Prasolov himself directs the work of the section on geography, cartography and classification, the activities of which are not confined merely to Russian soils. The Russians have long been interested in the application of their ideas of soil zonality to the rest of the world, and Prasolov has recently produced a new soil map of the world for inclusion in the Large Soviet Atlas. More detailed studies of the literature on the soils, vegetation, etc., of other regions have led to the production of new soil maps of Africa, South America and Australia. These maps and their accompanying memoirs, when they become generally available, should give a good picture of the extent to which the Russian conceptions of soil types can be applied to the more tropical countries.

For the U.S.S.R., one of the principal tasks of the cartography department is the preparation of a soil map of the Union on the scale of 1 : 1,000,000 which will be the standard map for the whole country. During the War, the surveys of the Institute were found of great use in the transfer of agriculture to the eastern regions, and considerable work is being done in the Urals, Kazakstan and Uzbekistan. While general soil surveys form an important part of the Institute's work, special surveys in connexion with erosion and salinization are also made and form the basis for the study of these phenomena and of methods of dealing with the practical aspects.

The weathering of rocks and minerals is the first stage in soil formation and is receiving considerable attention in the Institute. An interesting study is being made of the ash content of plants and the rock or soil on which they grow, and it has been shown that in the red Georgian soils there is a considerable movement of aluminium between the soil and certain plants in the natural vegetation; for example, hornbeam, beech and rhododendron. This fact has an obvious bearing on the relative movement of the soil constituents during development of the soil. In a study of rock weathering and soil formation under lichens, it is concluded that biological influence may be an important factor in the formation of clay minerals of the montmorillonite type.

The study of the nature and distribution of the clay minerals in soils has received close attention and a large body of data has been obtained. In addition to the usual X-ray and thermal methods of examination, use is being made of an electron diffraction method with some success. Other laboratory studies include exchange reactions, the nature of soil acidity, soil solution by high-pressure extraction and the nature of soil aggregates. The study of aggregates is made from the physico-chemical aspect with the view of elucidating their structure and origin in the various soil types, and also from the purely physical aspect to obtain a measure of their resistance to the destructive influences of erosion. The first aspect is an elaborate study involving microscopic examination of the aggregate at the different stages of the chemical treatment. The interesting result of the case of chernozem aggregates is that the clay minerals seem to be wrapped round the organic matter, resulting in a very stable aggregate.

Of the out-stations set up for the study of soils *in situ*, the best equipped, namely, those in the podzol and chernozem zones, suffered greatly during the War and work on them has had to be begun afresh. Some valuable results had, however, been obtained. It has been found that there is a seasonal shifting of the carbonate horizon of the chernozem up and down in the soil, the range of movement depending on meteorological conditions, but in one year reaching as much as 17 cm. This seasonal migration of carbonates impedes the loss of calcium from the rooting zone and so results in the chernozem being an extremely stable type.

While this account of the work going on in the Dokuchaiev Institute is necessarily brief, mention must be made of the soil museum which is still housed in Leningrad. It is one of the most complete collections of Russian soils and forms a valuable guide to the soil geography of the country. Since soil excursions were not possible during our visit, it was a most useful refresher to be conducted round the museum by its curator, Miss Shokalskaya, and have its contents explained by her in excellent English.

Recent articles in *Nature* have referred to the very fine geochemical studies being carried out in the U.S.S.R., and since these have an obvious bearing on certain soil problems, we were glad to have the opportunity of visiting the Vernadsky Laboratory of Geochemical Problems of the Academy. In this institute, under A. P. Vinogradov, there is going on a great amount of work on the distribution of the minor elements in soils and biological materials. The laboratories are very well equipped with modern physical apparatus, including X-ray spectrographs and recording photometers. One of the principal tasks of the institute is the construction of a map showing the geochemical provinces of the U.S.S.R., and considerable attention is being paid to the relation of endemic diseases and minor element distribution.

(*To be continued.*)

THE INFERIORITY COMPLEX AND THE PARANOID TENDENCY: WITH A BRIEF REFERENCE TO NAZI PSYCHOLOGY[*]

By DR. WILLIAM BROWN
University of Oxford

THE subject-matter of this essay has a very important bearing upon the world problems of the present day. The popular conception of the inferiority complex has become a scandal in modern psychology. It is a term easy to use, and it has suffered a fate somewhat similar to that of the word 'idea' in John Locke's "Essay Concerning Human Understanding" (1690). In that work he used the term 'idea' in a special sense, as illustrated in his definition ("Essay", Bk. I, Chap. i, § 8): "whatsoever is the object of the understanding when a man thinks". The general line of his argument was "the new way of ideas", of which Stillingfleet spoke—disapprovingly—on the first appearance of the "Essay". But Locke himself used the word in several different ways, and very soon it got into the general vocabulary of English literature in a large number of senses. That is an aftermath of Locke's important work.

Misuse of the Term 'Inferiority Complex'

It seems fated that the term 'inferiority complex', which had a fairly definite meaning when originally developed by the late Dr. Alfred Adler and some of his followers, should come into general use in so vague a form as to be of practically no value for the man of science. It is misleading because it gives an air of profundity to statements which are extremely elementary and superficial. Here I am not criticizing Adler's general position in the succession of the great medical psychologists, Sigmund Freud and C. G. Jung. We have much to learn from all three of them. Each has a message and to each belongs much solid research work on the mind. But it is a little unfortunate that Adler's position in psychology should be so much easier to understand at first blush than the systems of Freud and Jung. The result has been that it has attracted popular thought and opinion because of its simplicity, and has discouraged deeper consideration of these problems by the general educated public.

I am not at all sure that it was Alfred Adler himself who first used the term 'inferiority complex'. He spoke first of 'organ-inferiority' (*Minderwertigkeit von Organen*), a physical deficiency to which individuals react physiologically and psychologically in different compensatory ways. Adler's book on "The Neurotic Constitution"[†] contains much fundamental discussion along this line of thought. But when he came to deal more closely with the mind and its reactions, someone or other—I do not know who—introduced the term 'complex' in popularizing his psychological point of view: a word much used in those days, starting with Freud's 'Œdipus complex', and Jung's use of the term as meaning a repressed system of ideas with an emotional colouring, revealing itself in consciousness in a *disguised* form. So the word became attached to inferiority—*Minderwertigkeit*. This 'feeling of inferiority', *Minderwertigkeitsgefühl*, which in some respects we all share in one direction or another, undergoes (through repression) transformation in various ways to become an 'inferiority complex'—in other words, the total mind reacts to the feeling of inferiority, with all manner of results in thinking, feeling and behaviour.

Every one of us is, of course, inferior in some direction or other. No one can do everything well. A man may be a genius in some directions, but a dunce in others. We have to accept our limitations, recognize them for what they are, realize that nothing can be done about it, and push on with those lines of activity in which we are outstanding, or relatively normal and efficient. If we attach an excessive value to certain abilities and powers, artistic or intellectual or whatever they may be, which we ourselves do not possess to any great extent, but wish we did, we may come to imagine ourselves possessing them in a greater degree than we do, so that a certain distortion appears in our mental outlook. We are no longer single-minded, honest-to-goodness people moving forward with all the forces at our disposal; we begin to pretend to be something which we are not, and we deceive ourselves, and perhaps—which is less likely—deceive others. Man is the only animal capable of deceiving himself, and that self-deception accounts for many of the troubles of the world. We do not like to admit our inferiority even to ourselves, and in hiding it, we develop an inferiority complex. We pass from a '*feeling* of inferiority', which is straightforward and unblamable, to develop an '*inferiority complex*', a reaction which is not straightforward, which is a sin against our own nature, by pretending to be what we are not, and putting up a mere façade in the sight of the world.

Compensation and Over-compensation

In trying to hide our inferiority from ourselves we may over-compensate. There is an automatic tendency in any organism to compensate for deficiency, but it is easy to compensate to excess. A familiar example is the youth who is by nature diffident, retreating, and shy; and who, as a result of over-compensation, develops a blustering and swaggering attitude. Again, many people compensate for lack of success by imagining it, and as they give way to their phantasies and day-dreams, they come at last to believe that they have the power or to pretend that they have it, while at the same time retreating from any actual test.

---

[*] Based on a lecture delivered at Christ Church, Oxford, on November 25, 1944.

[†] Translation by B. Glueck and J. E. Lind (New York: Moffat, Yard and Co., 1917).

An alternative reaction is just to fall ill, when confronted with a real test. The person concerned may suffer with headache, anxiety, depression, sleeplessness, loss of appetite—general symptoms which cannot in his case be explained in terms of physical disease, but are quickly understood by one who knows the real situation. There are these various possible reactions to the feeling of inferiority, and they are evidence of the existence of the complex—a complex involving self-deception, which nevertheless is not quite complete. The term should be used only to describe *a distorted conscious reaction in the mind of the individual to a repressed or rejected feeling of inferiority*.

The general public, including some journalists, in seizing upon this term, have used it almost invariably in the wrong sense. They talk of 'inferiority complex' when what they have in mind is simply the fully conscious awareness by an individual of his inferiority in some direction or other—a very different thing. But although the inferiority complex is a further stage of complication in the mind, a stage beyond the clear consciousness of inadequacy, a disguise, a mask, a distortion, a camouflage, it is a very superficial form of disguise. The inferiority complex—using the term in its exact sense—is not very important and is easily dealt with. Those, for example, who wish to become psychotherapists, and get themselves analysed in order, so to speak, to have a mental cleansing before starting work, get rid of their inferiority complexes fairly quickly in the course of their analysis. The inferiority complex is at a relatively superficial level of the mind, and the more unconscious levels have yet to be reached.

Deeper Analysis

I found it not surprising, when in 1926 I came to know Alfred Adler personally, that he did not consider it necessary to carry out really deep and prolonged analyses, even in special cases. I think that that attitude was unfortunate for the Adlerian development of psychology. Adler stated that he could generally sum up his patient in one or two interviews—an insult, really, to human nature to suggest that it can be so casually explored. To go deeper one must have recourse to Sigmund Freud's analytical method and general explanatory system (whatever one may think of his central theory), with its conception of *libido*, sexual energy in its widest sense, which supports and sustains the world, the Ἔρως of Greek philosophy and myth, rooted in the physical, and yet transcending this in æsthetic and spiritual insight and inspiration.

Directly the *libido* is brought in, we reach a much deeper level of the mind. The *libido* is relatively impersonal, as contrasted with the organized ego ; it is the *Id* (*das Es*), it is something below and beyond the individual and for the most part unconscious. The individual, as Jung said, is rather like a frail craft floating on the turbulent waters of the unconscious. Jung took the *libido* in a wider sense than that of Freud, as meaning instinctive energy in general, somewhat, though not exactly, like the *élan vital* of Bergson's philosophy. Using the conception in the narrower, Freudian sense, we find reactions of a complex nature, where love may be linked up at a primitive level with aggressiveness or destructiveness, with *sadism* as a result. Later, mental reactions to this sadism may produce an obsessed type of personality. At the level of the inferiority complex there is just wounded self-love, self-centredness. Self-love or narcissism, according to the Freudian theory, is a fixation of *libido* upon oneself. But it should be projected upon others and should result in the linking up of individuals in the group, sustaining the loyalty of the individuals of the group to a leader, where a leader is involved, and making the individuals "members one of another", to use the Pauline phrase.

This love or *libido* in its original form is both homosexual and heterosexual. It can be felt for individuals of the same as well as for those of the opposite sex. Freud held that there is a homosexual constituent of the *libido* in everyone, which normally becomes sublimated before and at adolescence. It emerges in feelings of friendship, good-fellowship and group loyalty. It is expressed in that beautiful lament of David for Jonathan (Samuel II, Ch. i, §§ 17–27), and in Shelley's "Adonais", his elegy on the death of Keats. On the heterosexual side, however, love or Eros is more deeply held, because here it has a physical function to serve, that of handing on the torch of life to the next generation, but it too becomes spiritualized in its higher forms. There is such a thing as "a love passing the love of women", and, higher still, that *Amor intellectualis Dei* which Spinoza took as the goal and guiding star of his system of philosophy.

The Paranoid Tendency

This leads me to the consideration of a mental tendency which in my research work in medical psychology I am learning to regard as of great importance, namely, the paranoid tendency. It is rooted in unconscious mental activity, at a deeper level than that supporting an inferiority complex, in relation to the development of the super-ego (the primitive psychological basis of conscience) by the processes of introjection and projection. This deeper root is its relation to the *libido*, mainly though not exclusively to the homosexual element in it. I am not yet sure to what extent the paranoid tendency may be linked up with heterosexual *libido* ; it may be not infrequently so. But in full-blown paranoia, where the paranoid tendency appears in, as it were, pure culture, repressed homosexuality seems to be invariably present and the main cause of the delusional system (*Wahnsystem*).

This condition of paranoia, which has a hereditary basis, is not so rare a mental illness as the few cases seen in mental hospitals would suggest. It is more a general type of character and personality than a special mental disease or psychosis, with *fanaticism* as an outstanding characteristic. The paranoiac is born rather than made, and if his family history be inquired into there will generally be found some evidence of the same tendency in previous generations, showing itself sporadically in the family tree. The trouble about the paranoiac is that he is detected and dealt with only when he becomes an evident danger to himself and to others. It is then that he is placed in a mental hospital. But few paranoiacs are found in mental hospitals—the broken-down failures in this line of personality ! The majority of them escape general notice and detection and are out in the world, causing a great deal of family and social disturbance. I venture to say that they are a greater danger to world peace than any other type of mental abnormality. The earlier they are tracked down the better.

But the 'paranoid tendency', which is not identical with paranoia, is still more widespread, and may appear in everyone at some time or other, manifesting itself unmistakably under some particular mental stimulus or provocation. I mean by the paranoid tendency a general disposition to misjudge people, to become suspicious without adequate grounds, to feel that people are working against one when they are not really doing so. The main psychological mechanism involved is that of projection—a projection of the person's aggressiveness and hostility upon others. The tendency is to be explained by the fact that the individual does not fully understand himself and has inadequate control of his excessive aggressiveness.

A person suffering from paranoia, as distinct from the more general paranoid tendency, is usually of a very aggressive temperament, and because of that, his *libido* has a very rough passage in his mental development. Usually he does not 'get on with' the other sex. The homosexual constituent in his *libido* is more pronounced than the heterosexual. His aggressiveness also is linked up with feelings towards his own sex, with homosexual tendencies which have been repressed instead of being adequately sublimated. The homosexuality is not admitted by the person concerned; it is rejected and denied. Under repression, the love is actually turned to hate in the unconscious. This hate is then 'projected' upon the other person. He believes that this other person hates him and therefore persecutes him. The person whom he was ready to love but would not allow himself to love becomes in imagination his persecutor.

Thus the development of persecution mania begins. It is one stage in the development of the average paranoiac. But he may go further and for two alternative reasons develop megalomania. The ordinary explanation of the development of megalomania is that the individual supposes himself persecuted and then asks himself, "Why are all these people against me?" He comes to the conclusion that he must be a very important person if all these others find it necessary to combine against him in this way. He may go so far in his vision of himself as to consider that he is a kind of Messiah, with a special mission.

The other alternative is Freud's explanation, that the *libido* in such a case is withdrawn altogether from the outer world, and fixed upon the self or ego, thus narcissistically inflating the ego, and producing a regression to infantile narcissism. Megalomania, in Freud's view, is of an infantile nature, and represents a regression or step back from sublimated homosexuality to the infantile stage of narcissism, or fixation of *libido* upon the ego*.

Thus we have the two fundamental characteristics of full-blown paranoia: persecution mania (*Verfolgungswahn*), and megalomania (*Grössenwahn*). Paranoia is well defined in Kraepelin's words as "the insidious development, following from inner causes, of a lasting unshakable delusional system (*Wahnsystem*), which proceeds with complete preservation of clearness in thinking, willing and acting".

But the paranoid tendency is of much wider incidence, revealing itself in relatively normal individuals in special mental situations, with wrongful imputing of motives and misunderstanding of intentions, so that such people are unnecessarily suspicious and 'on the defensive', taking offence where none is intended and "fleeing where none pursueth". The tendency is linked up with aggressiveness and possibly with the (incompletely sublimated) homosexual constituent of the *libido*, and with a distorted development of the super-ego through the processes of introjection and projection which occur in the young child's mind in relation to parents, nurses, etc.

The Situation in Germany

This discussion has an important bearing on the psychological situation in Germany to-day. Many people are content to sum up the problem from the psychological side by saying simply and baldly, "Germany has an inferiority complex", "Hitler had an inferiority complex". No doubt both leader and nation had inferiority complexes in full measure, but these superficial distortions of their minds are not adequate to explain their outrageous behaviour in the last few years. It is something deeper than an inferiority complex which is concerned in the German problem, namely, a paranoid tendency. I have always said that Hitler was a paranoid personality. He was already suffering from some degree of persecution mania and megalomania in the days of his rise to power. The state of his mind was very characteristically shown in his reactions to the Jewish problem in Vienna, as described in Chapter 2 of "Mein Kampf". Hitler's reactions to Jewry and to Bolshevism were paranoid reactions. The line he took, that "terror must be met by terror", is the attitude of the paranoid personality. He was always in a state of defence, arming himself against what must have been at first an imaginary situation, however real it may have become later on owing to his own acts.

No one can be paranoid who fully understands himself. Hitler did not understand himself. To himself he was a knight in shining armour; and the people of Germany, after long-continued disappointment and frustration, came to accept him at his own valuation, especially when he received the support of the military and of 'big business'. The nation had lost its way, and here it found someone who seemed to believe in himself, and accordingly it came to believe in him. The paranoid person, on the surface, does believe in himself; so, for that matter, does the real Messiah, but Hitler was a false and not a real Messiah*.

The people rallied to him, step by step—I need not go into the history of the rise of National Socialism in Germany. He collected around him a number of paranoid individuals, or at any rate psychopathic personalities. The Nazi leaders seem all to be, or to have been, more or less abnormal.

Spread of the Paranoid Tendency

The psychological consequences of all this in the development of the German nation are clear. The people had become desperate and had lost their way. They were encouraged to be aggressive because they were told, and believed, that they were encircled again, and that others wanted to wipe them out. That was the very simple propaganda repeated by Goebbels on every occasion. "This war which was forced upon us. . . ." Goebbels revealed himself most clearly as a classic example of 'acquired paranoia'

---

* Sigmund Freud, "Collected Papers", 3, 449–452 (Hogarth Press, 1925).

* Hitler was also hysterical, and suffered from hysterical blindness at the end of the War of 1914–18 (see "Mein Kampf", p. 223 in the German edition).

(if one may coin such a phrase) in some of his weekly articles in the Nazi publication, *Das Reich*. In the literal sense, of course, paranoia cannot be acquired; it is inborn in the individual, but it can take a collective form which is acquired in the group. It has been pointed out by psychologists that as soon as a group is formed the paranoid tendency may spring up as a collective characteristic*. It seems to be a fundamental tendency in group psychology. One group may become paranoid in relation to another. Groups of all kinds link up or develop hostilities towards one another; and if their members are put into uniform the paranoid tendency is magnified.

Germany is going to be one of the great political and psychological problems of the next generation. It is a problem which will require to be dealt with in a strictly scientific way, by the accumulation of facts, not of phantasies or rumours, and the arrangement of such facts in relation to possible hypotheses, which must be tested and confirmed. To this problem some Germans themselves will make valuable contributions. It will be a problem for us all for a generation, for it cannot be left unsolved. We cannot leave a political vacuum in the middle of Europe.

The above essay was written before the cessation of hostilities. But now that Germany and Japan have been completely defeated and the atomic bomb has been invented and used, national mentality and the group mind are in need of understanding and control as never before. It is easier for an atom bomb to wipe out a city than a mental complex. The sciences of psychology, sociology and politics must not fall too far behind the physical sciences in their future development, if ultimate disaster is to be avoided.

NEWS and VIEWS

New Sibthorpian Professor at Oxford: Mr. G. E. Blackman

MR. GEOFFREY BLACKMAN, son of Prof. V. H. Blackman, goes to Oxford next term as Sibthorpian professor of rural economy. He succeeds Prof. J. A. Scott Watson, who last year joined the Ministry of Agriculture as chief education and advisory officer. Mr. Blackman was educated at King's College School, and at Cambridge (St. John's) where he took both parts of the Natural Sciences Tripos. After a year of postgraduate work in the Soil Physics Department at Rothamsted, he took up, in 1927, the headship of the Botany Section of the Jealott's Hill Research Station, Berkshire, then newly established by Imperial Chemical Industries, Ltd. In one sense his researches during his eight years tenure of the post were directed to practical ends, such as the improvement of pasture by various combinations of fertilizer and grazing treatments, and the use of various chemicals in the control of weeds. But he contributed materially to the application of modern statistical methods to the botanical analysis of pastures and, what was more important from the long-term point of view, played his part, along with the Aberystwyth workers and others, in developing the ecological approach to grassland problems and to those of weed-crop competition.

Since 1935, Mr. Blackman has been lecturer in plant ecology at the Imperial College, London. He was also, for three years before the War, assistant science editor of the *Gardeners' Chronicle* and, since 1942, has been honorary secretary of Biology War Committee. Also, since 1941, he has headed a team of workers, under the Agricultural Research Council, who have been engaged on two major projects. One is the introduction from overseas of improved varieties of oil seeds (sunflower, soya bean and linseed) and maize. This work is still in progress, but has already shown that certain North American linseeds are greatly superior to the mixed La Plata type previously grown; that sunflower seed of good quality can be produced in Britain; and that certain of the new hybrid types of maize, from the northern United States and Canada, have great promise as forage crops, and especially as silage crops, in southern England. The other project has been a continuation of the long search for more effective and more highly selective herbicides. The practical results already achieved are very important. For example, sulphuric acid, in appropriate concentration, has almost eliminated the laborious process of weeding onion crops; copper nitrate, copper chloride and the sodium salt of di-nitro-*ortho*-cresol can be safely and effectively used on flax. Sulphuric acid, applied before the emergence of crop seedlings, is of great value in the case of crops such as carrots and beet which, on account of their slow initial growth, are specially liable to be smothered by quick-growing annuals. But most remarkable has been the discovery that certain plant-growth substances, applied at rates of the order of a pound per acre, completely destroy certain species and leave others quite unharmed. One of these materials (C.L.C.), which will soon be available in quantity, is very strongly toxic to a large number of dicotyledonous plants, and harmless to cereals and most other monocotyledons. It is to be hoped that Mr. Blackman will find at Oxford time and facilities to continue this extremely profitable line of work.

Advisory Committee on Atomic Energy

IN reply to several questions asked in the House of Commons, the Prime Minister has stated that many questions involved in the future of atomic energy, including that of the international handling of the subject and its possible development for industrial purposes, are engaging the attention of the Government. To assist the Government in dealing with the far-reaching questions raised by the discovery, both as regards its international treatment and its further development in Britain, whether for industrial or military purposes, the Government has appointed the following advisory committee: Sir John Anderson (chairman), Sir Alexander Cadogan, Permanent Under-Secretary of State, Foreign Office; Field-Marshal Sir Alan Brooke, chief of the Imperial General Staff; Sir Alan Barlow, Second Secretary of the Treasury; Sir Edward Appleton, secretary of the Department of Scientific and Industrial Research; Sir Henry Dale, president of the Royal Society; Prof. P. M. S. Blackett, Langworthy professor of physics in the University of Birmingham; Sir James Chadwick, professor of physics in the University of Liverpool; and Sir George Thomson, professor of physics at the Imperial College of Science and Technology, London. In response to further questions as to the precise functions of this committee, Mr. Attlee stated that it will advise the Government both with regard to the scientific progress and the general background of the whole subject, but that the Government itself will decide questions of policy arising out of the discovery.

The True Foundations of Peace

THE recently published draft proposals for an Educational and Cultural Organization of the United Nations (London: H.M. Stationery Office. *2d.* net) have received the welcome due to a document answering to one of the first needs of the hour. Ever since 1942, discussions among Ministers of Education or their equivalent in the United Nations have taken place, and the organization now proposed has developed therefrom. In these discussions, Mr. R. A. Butler took an active part from the first. The draft proposals will form the basis of discussion at a conference to be opened in London on November 1. That conference will be one of the first results of the San Francisco deliberations, and the organization in question will be the first "specialized agency" to come into being under the relevant clause of the United Nations Charter.

The cardinal aim of the organization is "to develop and maintain mutual understanding and appreciation of the life and culture, the arts, the humanities and the sciences of the peoples of the world". This truly magnificent aim the organization will seek to further by various means. It will facilitate consultation among leaders in educational and cultural life, assist the free flow of ideas and information through every established medium with special attention to the exchange of information on educational and cultural developments, including advances in scientific knowledge, foster the growth in each country of measures to give support to international peace and security, conduct and encourage research into the problems related to the maintenance of peace and advancement of welfare, and assist countries that need and request help in developing their educational and cultural activities. The organization will operate through a conference, an executive board, and a secretariat. It is intended that the conference shall meet at least once a year and that all activities related to the functions of the organization shall be reported periodically. It is to be hoped that the conference to be opened in London on November 1 will be the beginning of great things in the cause of human progress and welfare.

Books and Journals for Holland and Denmark

INFORMATION regarding the conditions of life in scientific departments is beginning to come from Central Europe. After privations of various kinds Prof. O. Winge, Dr. Westergaard, Dr. A. Skovsted and Dr. C. A. Jorgensen in Denmark have now returned to their posts. One of their greatest difficulties is that they have been cut off from all knowledge of science in the rest of the world, and they are in great need of scientific journals, reprints and similar information. The conditions in Holland and France are even worse, since in many cases the Germans removed anything of scientific value that they could lay their hands on. It is possible to send letterpress to Sweden, Denmark, France and Holland through the Censor in Charge, Postal and Telegraph Censorship Dept. Permit Branch, Aintree, Liverpool, if these are marked "Paragraph 42" and the weight does not exceed 1 oz. for Holland and Denmark, or 4 lb. for Sweden and France. Dr. F. W. Sansome, Botanical Department, University, Manchester, 13, to whom we are indebted for the above information, states that he would be glad to aid in the transmission of such parcels if any difficulty is met with in transmission through the normal channels.

Nietzsche and Science

MARIO BUNGE (*Revista Continental de Filosofia*, 2, No. 4, Nov.–Dec. 1944) has written a useful perspective of Nietzsche's attitude towards science. Nietzsche's main ideas are both anti-scientific and anti-rational, and his own confession, "I know very little about the results of science", was quite unnecessary, as is obvious from the puerility of his views on different sciences. Apart from his great influence on contemporary thought—which is not always recognized—he was a typical product of the decadence of European culture, and in general of the decadence of the philosophy which originated with positivism and culminated in the modern anti-intellectualism. Hence, Bunge says, we may say that Nietzsche is not only the direct forerunner, but also to a large extent the characteristic exponent, of so-called modern philosophy. He attempted to destroy standards of values and to create others, and he made no secret of the fact that those he wished to destroy were cultural—the scientific, philosophical, ethical, æsthetic, religious, etc., and above all, the social and political values which were an obstruction to the *junker* class. His attitude towards cultural interests is seen in his reply to the question, "What is science ?", and the whole epistemology of Nietzsche is summed up in this reply: "It is the experience of men for their instincts and the instinct to know their instincts." The *summum bonum* is the instinctive life, not just an animal existence, but the free manifestation of the desire for domination ; not the longing for quiet joy, but the peril of action, the struggle, and through this the ascendancy. Nietzsche had no desire for science but for knowledge ; though not knowledge of the contemplative kind, but a knowledge active and authoritative. His ideas do not constitute so much a system of philosophy as a vague and obscure vision of the world, more suitable to a demoniac than to a philosopher seeking truth. In short, one might say that his attitude to science is, generally speaking, negative ; and when it is not that, it is something much worse—a restrained pretence but brutal and also pragmatic in the worst sense, namely, that of the prostitution of science as a priestess of Moloch.

British Universities

IN *Britain To-Day* of May 1945 (No. 109), Sir Charles Grant Robertson, in an article entitled "The Idea of a University", analyses some of the characteristics of British universities as a whole. He discusses their claim to contribute an interpretation of life, built up through centuries of effort and travail, which has enabled them to survive grim ordeals and emerge stronger and purified by the struggle and which embodies the fundamentals of any civilization worth the name. First, Oxford and Cambridge and, through them, the modern universities represent in an unbroken tradition and growth the medieval ideal. Secondly, no British university has been created, endowed or maintained by the State, and until 1920 the State did not contribute either to capital or to income expenditure. Thirdly, British universities are now co-educational, and the one imperative condition imposed on them is that unqualified persons should not be let loose on the community. Fourthly, the universities, if not the sole, are the main avenues to the professions and to all branches of teaching. They are second to none in the range and quality of their studies, equipment and teaching, and the demand for strengthening every form of research comes primarily from the universities, because their staffs know what can and ought to be done, and enlighten the community by doing it. Finally, after emphasizing that the freedom and independence of British universities are a sure guarantee of their capacity to meet the needs of the future, Sir Charles insists that, in accordance with the medieval ideal, a university is not a real university unless its members pray together, work together and play together.

New Film-Strip Projector

In the field of education, the post-war period is likely to be characterized by a marked increase in the use of visual aids. The ordinary lantern will most probably be replaced, except for large audiences, by the film-strip projector. The advantages of this newer form of projector are many and do not require elaboration. Further, it is likely that the film-strip projector will be used for educational purposes in conjunction with a sub-standard cinematograph projector; for, to-day, the complete visual unit comprises a film together with film-strips, charts, etc. Although a few associations have concerned themselves with visual education during recent years, progress has not been possible because of the lack of projectors for films and film-strips. To-day, the outlook is brighter, and Messrs. Dufay-Chromex, Ltd., 14 Cockspur Street, London, S.W.1, announce that they will have a new film-strip projector on the market in the near future. It is of attractive design and incorporates many new ideas which have been developed while the machine has been in use with various Service Departments. Several features are worthy of special mention. The gate is modelled on that of a cinematograph projector, and traction of the strip is effected by a lever which, with a single movement, advances the strip one frame. The gate is adaptable for three sizes of frame which are in common use. The optical unit merely slides in the lamp house, thus permitting the easy replacement of a projection lamp. The film is kept flat in the gate by a glass plate, the pressure on which is removed as the film is passed through.

Earthquakes During the First Quarter of 1945

During the first quarter of 1945, fourteen earthquakes were registered by the seismographs at King's College Observatory, Aberdeen, and Dr. A. E. M. Geddes reports that the instruments were not working during March 7–21. The largest shock was on February 10, registered at Aberdeen at 05h. 9m. 48s. G.M.T. from an epicentre estimated distant 77·4°, and developed a maximum ground amplitude on the east component at Aberdeen of 178 μ at 05h. 36m. 11s. G.M.T. At the Dominion Observatory at Wellington, New Zealand, six strong earthquakes were registered during February and five during March. The earthquake on February 26, with epicentre about 77° from Wellington, was a deep-focus shock, the focus being 180–200 km. below the surface of the earth. The earthquake of March 18 had its epicentre south o the Kermedecs, only about 7 km. distant from Auckland, New Zealand. The greatest felt earthquake in New Zealand during February occurred on the 18th and was felt in north-west Nelson with intensity on the modified Mercalli scale of 4. During March fifteen earthquakes were felt in New Zealand, the greatest intensity being scale 4 at New Plymouth on March 11, in the northern part of South Island and the Cook Strait region on March 12, at Wairoaton on March 19 and at Masterton on March 19 (separate shock).

During March, twelve earthquakes and tremors were registered by the seismographs at the geophysical observatory at Toledo, Spain. The strongest of these was on March 18; *iPz* registered at 00h. 09m. 33s G.M.T. from an epicentre some 76° distant, and a ground amplitude of 35 μ was attained at Toledo at 00h. 33m. 21s. G.M.T. The United States Coast and Geodetic Survey, in co-operation with Science Service and the Jesuit Seismological Association, has determined the provisional epicentre of the earthquake of March 17, using reports from ten seismographic observatories, to be at lat. 6·9° N., long. 78·0° W., which is off Colombia.

Announcements

The centenary celebrations of the Imperial College of Science and Technology, London, will take place during October 25–27. The opening meeting will be held in the Albert Hall, and will be attended by the King, as visitor of the College, who will be accompanied by the Queen.

The fifth series of postgraduate lectures arranged by the London Section of the Oil and Colour Chemists' Association will be delivered by Prof. E. N. da C. Andrade, who will speak on "Viscosity and Plasticity". The lectures will be given at the Royal Institution, Albemarle Street, London, on October 11, 18 and 25, at 6.30 p.m. Admission will be by ticket only (price 10*s*.), applications for which must be sent to David E. Roe, c/o Atlas Preservative Co., Ltd., Fraser Road, Erith, Kent.

The following appointments in the Colonial Services have been made: J. McA. Todd, to be plant pathologist, Gold Coast; R. E. T. Hobbs, agricultural officer, Kenya, to be senior agricultural officer, Kenya; A. C. Maher, agricultural officer, Kenya, to be senior soil conservation officer, Kenya; O. S. Swainson, principal agricultural officer, Nigeria, to be senior agricultural officer, Zanzibar; T. Y. Watson, agricultural officer, Kenya, to be senior agricultural officer, Kenya; I. R. Dale, assistant conservator of forests, Uganda, to be senior assistant conservator of forests, Uganda; A. Foggie, assistant conservator of forests, Nigeria, to be senior assistant conservator of forests, Nigeria; J. C. Rammell, senior assistant conservator of forests, Kenya, to be conservator of forests, Kenya.

The Museum Book Store, Ltd., 45, Museum Street, London, W.C.1, state that they have acquired the library of the late Prof. Hans Sachs (see *Nature*, May 19). The collection includes long runs of the *Centralblatt für Bacteriologie*, *Zeitschrift für Immunologie*, etc., and some ten thousand reprints in 119 labelled boxes. Particulars will be sent on request.

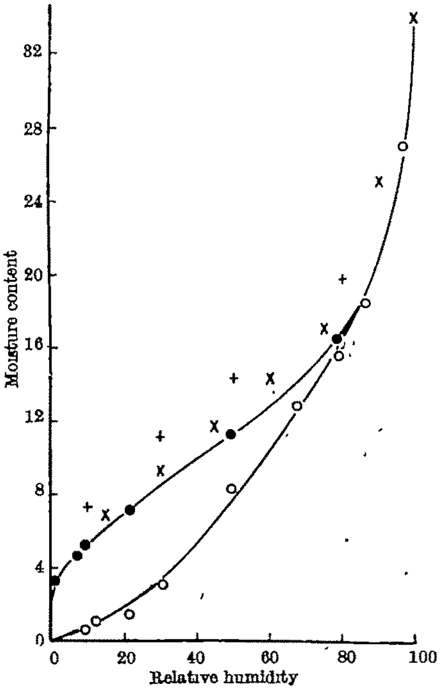
Hysteresis in the Adsorption of Water Vapour by Wheat

The water-vapour adsorption isotherm for wheat has been measured by several workers[1,2,3]. These measurements have been made under similar conditions; the wheat, which was initially at a moisture content corresponding to average storage conditions (~ 13·5 per cent of dry weight), was exposed to a series of atmospheres maintained at definite relative humidities. The equilibrium was attained in all measurements from a relatively high moisture content, and no attempt was made to study the phenomenon at extremely low relative humidities. In particular, no distinction was made between adsorption and desorption, so that it was not clear whether hysteresis was present or not.

Fairbrother[4] has reported that dried wheat flour does not completely regain its moisture content when re-exposed to the original relative humidity. He also found that wet and dry wheat, when mixed, do not reach equal moisture contents, that of the dry wheat always remaining about 2 per cent below that of the wet. Pap[5] and Ankers, Geddes and Bailey[6] have substantiated these observations. It appears from this that hysteresis is present in the adsorption of water vapour by wheat, and Fairbrother has suggested it as an explanation of his observations.

In the course of some work in this laboratory, we have measured the equilibrium moisture content for some No. 1 Garnet wheat at various relative humidities for both increasing and decreasing relative humidities; a very definite hysteresis has been found. This is shown in the accompanying graph, where for comparison purposes the results of Coleman and Fellows[1] and those of Gane[2] have been reproduced. The measurements in this work were made by means of a McBain sorption balance, and all moisture changes were carried out in an atmosphere of water vapour, the air being completely exhausted from the apparatus. The relative humidities were maintained by means of saturated solutions and were measured with a vacuum oil manometer. The temperature of the measurements was 24·5° C.

The slope of an adsorption isotherm at any point gives the change of moisture content per unit change in relative humidity. This quantity is analogous to the specific heat in the corresponding relation between heat content and temperature, and Daynes[7], in considering adsorption by rubber, has called it the 'specific solubility' and designated it by the symbol S_h. Daynes[8] has pointed out that with an adsorption isotherm such as that of rubber, which is convex towards the humidity axis, S_h increases rapidly as the moisture content increases, and the approach to equilibrium at high humidities is a very slow process. On the other hand, in drying, S_h becomes progressively smaller as the humidity is reduced, and desorption proceeds rapidly and quickly approaches an end-point. The reverse of this effect has been observed with leather, which has been found to take up moisture quickly and to be very slow in drying[9]. On Daynes' reasoning this is the result of the fact that the isotherm for leather is concave to the humidity axis.



○, adsorption; ●, desorption; ×, Coleman and Fellows' average for hard red winter wheat at 25° C.; +, Gane, weak wheat at 20° C.

When hysteresis is present, the 'specific solubility' will not be the same for adsorption and desorption. With an isotherm such as that shown, the adsorption curve is convex to the humidity axis throughout, while the lower part of the desorption branch is concave. We should therefore expect a progressively slow up-take of moisture such as is found with rubber and, equally, a slow drying corresponding to that observed with leather. In point of fact, moisture changes do take place slowly with wheat, but it is with the drying of wheat at low humidities where the effect is most noticeable. It is a long and difficult process to extract the last few per cent of water from wheat by means of a desiccating agent or a vacuum; if the wheat is to be dried within a reasonable time, it is necessary to use a vacuum oven-drying method. The shape of the isotherm offers an explanation of these facts, for at low humidities the desorption branch becomes very steep and it would be necessary to extract a relatively large amount of moisture with a very small pressure difference. On the other hand, the adsorption curve is very flat at low humidities and in that region wheat will adsorb moisture very rapidly; it is only at high humidities that the adsorption process becomes slow.

It should be pointed out that the high 'specific solubility' is not necessarily the only factor which tends to make the drying of wheat at low moisture contents so difficult; it is probable that the coefficient of diffusion of water vapour through the wheat decreases very rapidly at low humidities. King[10] has shown that the diffusion constant for keratin becomes extremely small at moisture contents below 6 per cent, and Glückauf[11] has pointed out a similar effect with a hair hydrometer. For these substances then, moisture changes at low relative humidities would take place at a slow rate owing to the small value of the coefficient of diffusion, and it is exceedingly probable that a similar effect exists in wheat. The change in the 'specific solubility', however, exerts a differential effect since it is just at the extremely low vapour pressure, where the adsorption branch is very flat, that the desorption curve becomes almost vertical. Thus while dry wheat will take up moisture and come very quickly to equilibrium at low humidities, the opposite process of desorption is extremely slow.

Cosmic Rays and Kinematical Relativity

MILNE[1] suggests that the undulatory component of cosmic rays may be the remains of the radiation of very high frequency the existence of which in the remote past I postulated[2] in connexion with the origin of the planets. I do not think that this idea can be accepted without a slight modification which, however, covers the particulate component as well. Consider a photon such as I postulated which had an energy of 6×10^{44} ergs at time $t=2 \times 10^{-63}$ sec. If it reached the earth to-day, then at that time in the past it was in the neighbourhood of a galaxy receding from our own with almost the speed of light. Now, that is to say, with $t = 6 \times 10^{16}$ sec., its energy has been degraded by a factor of 3×10^{-80} by the Doppler effect, and is therefore only 2×10^{-34} erg. This is so even if it has undergone reflexion or refraction. Whereas the energies of cosmic ray photons may exceed an erg ($0 \cdot 6 \times 10^{12}$ electron-volts) and certainly exceed 10^{-6} erg. Moreover, each of the postulated past photons must now be represented by a very large number of photons, perhaps of the order of 10^{48}.

All these difficulties can be overcome if the energy of the cosmic rays has spent a large fraction of the dynamical time since the origin of the solar system not as the electromagnetic energy of radiation, but as the kinetic energy of moving particles, which, according to kinematical relativity, undergoes no degradation like that due to the Doppler effect. During dynamical time τ the energy of a photon relative to matter in its neighbourhood is degraded by a factor $e^{-\tau/t_0}$, where t_0 is about 2×10^9 years. In 3×10^{11} dynamical years most cosmic rays would pass through many galaxies, encountering gas or dust clouds much denser than any matter which may exist between the galaxies, giving opportunities for the transfer of energy between particles of different types, and between particles and photons, and also for the sharing of the energy of one particle or photon among a number of particles. All these events occur in our own atmosphere. Without further data one cannot be precise, but it would seem that most cosmic rays have spent most of dynamical time as particle energy rather than photon energy.

In fact, once the energy spectra of the several cosmic ray components which enter the atmosphere are known, it may be possible to calculate the corresponding spectra at a much earlier date by processes similar to those which are used in calculating the spectra of the 'primary' extra-atmospheric radiation from that at sea-level. If such calculations lead to reasonable consequences, it will be possible to accept the above hypothesis as a provisional account of the history of cosmic rays.

In a recent letter[3] Prof. Dingle suggests that I have been wasting my time in making unverifiable deductions from kinematical relativity. If these deductions are unverifiable I have certainly wasted my time, however true this theory may be. I venture to think that, since the theory which I have briefly adumbrated has fairly wide consequences for stellar evolution, it will be capable, if not of complete verification, at least of observational disproof if it is untrue. If it is so disproved, it may constitute a *reductio ad absurdum* of Milne's theory. In this case I am sure that Prof. Dingle will agree that the time spent in slaying such a Jabberwock has not been wasted.

For I cannot help suspecting that it has survived Prof. Dingle's vorpal blade. He writes that kinematical relativists cannot legitimately explain the Doppler effect by the relative motion of a light source and an observer, since a change of time-scale reduces relative motion to rest, and "we cannot attribute an objective fact to a cause destructible by an arbitrary act on the part of the thinker". This is only true if the arbitrary act does not substitute an equally valid cause (using his terminology, which is perhaps not the best possible in this context). If I break my nose on a lamp-post in the black-out I usually say that it was at rest and I ran into it. If I adopt egocentric co-ordinates I can say that I was at rest and it ran into me. If I use geocentric co-ordinates, I can say that it was moving eastwards at 648 m.p.h. and overtook me since I was only moving eastwards at 645 m.p.h. But all these accounts of the collision lead to the same calculable impulse on my nose. Milne's transformation is a deeper one, since relative motion is not invariant under it. But provided it leads to the same predictions of observable events, as (*pace* Prof. Dingle) it does, it would seem to be scientifically legitimate.

I do not think that it will be rejected on such grounds as Prof. Dingle suggests. But it will certainly be rejected if it consistently leads to false predictions of observable phenomena. At present our most powerful telescopes can only photograph light about 200 million years old, that is to say Permian light. As our backward range in time increases, the divergence between datings on the kinematical and dynamical scales will also increase, and it will become increasingly easy to reject theories which depend on this divergence, should they prove incorrect.

The agreement or disagreement with fact of calculations concerning cosmic rays will also serve as a test of the correctness of Milne's theory.

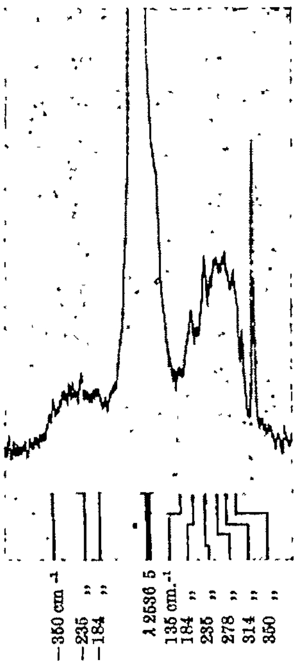
Raman and Infra-red Spectra of Rock-salt

Rasetti[1] succeeded in recording a Raman spectrum with rock-salt, using the 2537 A. radiations of the mercury arc as exciter. But as neither his preliminary report nor his subsequent paper with Fermi[2] gives quantitative details of the spectrum, it appeared desirable to investigate the subject afresh. In seeking to record the Raman effect with rock-salt, the presence of a disturbing effect became evident, namely, a luminescence exhibited by the crystal attended by the development of a fugitive coloration under the action of the ultra-violet rays. As the Raman spectrum is itself feeble, it is partially masked or even completely overpowered by the continuous spectrum of the luminescence. Ultimately, however, a specimen of rock-salt was found which was non-luminescent. Using this specimen, and with a fine slit which made prolonged exposures necessary, a spectrogram was obtained in which much more detail could be seen than in the picture reproduced with Rasetti and Fermi's paper. As is evident from its microphotometric record here reproduced, the spectrum consists of a series of Raman lines distinctly resolved from each other. The frequency shifts from the parent radiation of the more prominent of them are 135, 184, 235, 278*, 314* and 350* cm.$^{-1}$, while there are feebler lines with frequency shifts 202 and 258 cm.$^{-1}$. Further, there are indications that the three lines marked with an asterisk possess imperfectly resolved components.

It is worthy of note that Barnes and Czerny[3], investigating the infra-red absorption spectrum of sputtered films of rock-salt, found, besides the principal absorption peak at 163 cm.$^{-1}$, other absorption peaks at 190 and 245 cm.$^{-1}$, the latter being the more prominent. The experimental method of locating these peaks is sufficiently uncertain to justify our identifying their positions, at least tentatively, with that respectively of the two lines with frequency shifts 184 and 235 cm.$^{-1}$ which appear very prominently in the Raman spectrum. There is no Raman line with a shift 163 cm.$^{-1}$ corresponding to the frequency of the principal infra-red absorption; but this is not surprising as symmetry considerations[4] indicate that it should not appear in light-scattering. We may, however, tentatively identify the Raman line with frequency shift 314 or one of its components as the octave of the principal infra-red active vibration frequency.

The appearance with rock-salt of numerous clearly defined and well-resolved Raman lines, other than the octave of the so-called 'fundamental frequency' of the lattice, is clearly a matter of great theoretical interest. The theories of light-scattering in crystals[5,6] which are based on Born's postulate of the cyclic lattice, lead to the result that only the infra-red vibrations the length of the phase-waves of which satisfies the well-known Bragg formula in relation to that of the light waves, can give an observable effect. This is equivalent to the statement that only the so-called 'fundamental vibration frequencies of the crystal lattice' can appear in the Raman effect, and that all others are excluded. Pursuing the same train of thought to its logical conclusion, it can readily be shown that if the second-order terms in the variations of optical polarizability and/or the anharmonicity of the vibrations are considered, octaves and/or combinations of the 'fundamental vibration frequencies' may appear, and no others.



Microphotometric record of the Raman spectrum of rock-salt

In the attempt to escape the contradiction with the experimental facts which is manifest, we may give up the assumption (inherent in the postulate of the cyclic lattice) that the infra-red vibrations have coherent phase-relations over extended volumes in the crystal, and limit the region of assumed coherence of phase to volume elements the dimensions of which are large compared with an individual lattice cell, but are smaller than the wave-length of light. Even this change in the basis of the theoretical approach, however, does not resolve the difficulty. For, on the new basis, the entire continuous spectrum of the crystal as deduced from the Born dynamics should manifest itself as a second-order Raman spectrum of octaves and combinations. What we actually get, however, is something very different, namely, a set of discrete lines.

The contradiction between the experimental facts as observed with rock-salt and the consequences of the Born crystal dynamics would, therefore, seem to be inescapable.

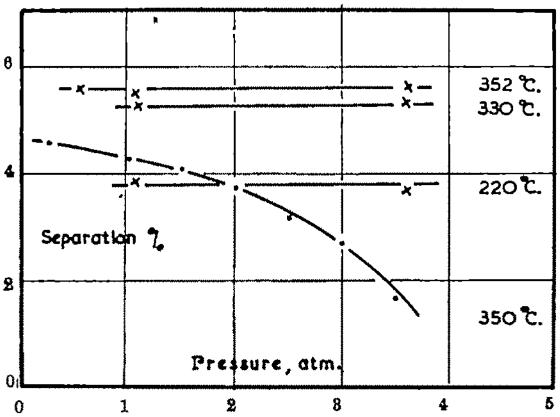
Effect of Pressure on Thermal Diffusion in Gases

Because of the present interest in the industrial application of thermal diffusion to the separation of gases, it is perhaps desirable to report some work concerned with the effect of pressure on the thermal diffusion process.

Schmahl and Schewe published measurements[1] of the separation produced by thermal diffusion in mixtures of hydrogen and hydrogen sulphide, and of hydrogen and carbon dioxide. The gas mixture was contained in two cylindrical bulbs, 2 cm. in diameter and 21 cm. and 7 cm. in length respectively. The bulbs were connected by a 5 mm. bore tube, 12 cm. long, which included a stopcock. While the larger vessel was heated in a furnace, the other was maintained at 20° C., and when equilibrium was attained the contents of the two bulbs were separately removed and analysed. The separation, that is the difference in composition of the gas in the two bulbs, found in this way in a hydrogen – carbon dioxide mixture at about 1 atm. pressure agreed well with values found by others. But measurements made at higher pressures showed a marked dependence of the separation on the gas pressure. Between 1 atm. and 3·5 atm. pressure the separation decreased by 50 per cent; it appeared that it would vanish at about 4 atm. pressure.

This result is unexpected. Theoretically, the separation is independent of the pressure, at least so long as multiple collisions among the molecules are negligible, and measurements over a small range of pressure[2] had so far confirmed the theory. Further measurements have therefore been carried out over the same range of pressure as in Schmahl and Schewe's experiments. An apparatus already described[3] was suitably modified and separation measurements for a hydrogen – carbon dioxide mixture containing 44 per cent hydrogen were made at pressures up to 3·6 atm. The gases were taken directly from cylinders, but the small amount of impurity is unlikely to be important. The results are shown in the accompanying graph, together with those of Schmahl and Schewe for a hydrogen – carbon dioxide mixture containing 32 per cent hydrogen. There is no indication of a pressure effect in the present measurements.



SEPARATION AS A FUNCTION OF PRESSURE FOR HYDROGEN – CARBON DIOXIDE MIXTURES.

—.—.— Schmahl and Schewe; 32 per cent hydrogen.

—x—x— Present results; 44 per cent hydrogen.

Temperatures refer to heated bulb; other bulb at 20° C. in all cases.

The explanation of the results of Schmahl and Schewe is not obvious, though it seems possible that insufficient time was allowed for equilibrium to be reached before the analyses were made. Experience in the present work suggests that, at the higher pressures, even the ten hours which Schmahl and Schewe sometimes allowed might be inadequate for separation to become complete in the long bulbs of small cross-section which they used.

Logarithmic Scales

THE suggestion recently put forward[1] that a logarithmic scale should be used for high-vacuum measurements directs attention to the fact that, while increasing use is being made of logarithmic scales as a basis of comparison, there is no generally recognized notation for this purpose.

The convenience of the decibel, as used in electrical communications, has prompted workers in other fields to adapt it to their own requirements; but in many cases this cannot be done, owing to the restrictions with which the decibel has, very properly, been circumscribed, making it solely a measure of relative energy flow. These restrictions increase its utility for the purposes of the telephone engineer, but preclude its use as a general method of expressing a ratio on a logarithmic basis.

Some form of logarithmic notation, corresponding to the decibel, can often be used with advantage wherever the response to a given excitation is either basically exponential or conveniently predictable as the product of a number of component factors. But to be most effective the notation should be as free from special restrictions as the older percentage basis of comparison.

For such a purpose, it is suggested that the term 'decilog' might be used, the decilog (dL) being analogous in all respects to the decibel, except that there is no restriction on the nature of the quantities being compared.

In most cases, one of these two quantities would be the reference level. Thus, a vacuum measurement would be expressed as so many decilogs below one bar, and the intensity of a physiological stimulus as so many decilogs above the threshold intensity, giving, incidentally, a linear response in terms of the Weber-Fechner law.

Again, in the design of technical amplifiers and electrical networks for purposes other than communications, voltage is frequently of more significance than power, and the impedance level may vary widely. In such circumstances, the gain or loss in decibels is meaningless, and the performance could more usefully be expressed in decilogs on a voltage basis.

There does, therefore, appear to be a need for some notation of this kind, and its general adoption would avoid the creation of a multiplicity of special 'units' to meet each individual application.

Frictional Properties of Wool Fibres

IN the course of work on the felting properties of wool a simple apparatus has been devised to examine the frictional properties of individual fibres in selected fluids. To each end of the clean fibre is fixed a copper hook (0·1 gm.) by means of molten shellac. The fibre is then suspended over a cylindrical rod of polished keratin (in the present experiments rhinoceros hide, diameter 7 mm., was used), and the requisite solution is allowed to drop rapidly on to the fibre-rod junction. A bent glass rod in contact with the underside of the cylinder carries away the used solution. Weights made from calibrated pieces of wire are then gradually added to one of the hooks until, with careful observation, preferably through a magnifying eyepiece, the fibre just commences to slide. The experiment is then repeated using the other hook and causing the fibre to move in the opposite direction.

In this way the forces required to slide the fibre with the scales and against the scales can be determined to the nearest 0·01 gm. The coefficient of friction in either direction is then calculated from the formula $W_1/W_2 = e^{\mu\pi}$, W_1, being the total load in the direction of motion and W_2 the weight of the hook plus shellac on the other end of the fibre. The above formula is dependent upon continuous contact between the fibre and the fixed surface and would not be applicable if the fibre is held at a few isolated points on the surface. That there is a continuous contact is evident from the reproducibility of results and from the gradual motion of the fibre, which is usually of the order of 0·5–3·0 cm. per minute. The effect of variations in the total load has been studied, and it has been found that variations within the range used (0·25–0·70 gm.) do not seriously alter values for the coefficient of friction. The method has been found to be inapplicable to dry surfaces.

Results obtained with fibres from untreated wool (64's quality Merino) and from the same wool when treated by some of the commercial unshrinkable processes are set out in the accompanying table. The solution used contained 0·2 per cent soap and 0·1 per cent sodium carbonate, and had a *p*H value of 10·7, the temperature being 30–35° C.

FRICTIONAL MEASUREMENTS ON UNTREATED AND NON-FELTING WOOLS.

Anti-scale coefficient $= \mu_1$

With scale coefficient $= \mu_2$

Directional coefficient $= \frac{\mu_1 - \mu_2}{\mu_1 + \mu_2}$ (term adopted by Mercer[1]).

Treatment	μ_1	μ_2	$\frac{\mu_1 - \mu_2}{\mu_1 + \mu_2}$
Untreated	0·28	0·10	0·47
	0·37	0·16	0·40
	0·34	0·15	0·39
Sulphuryl chloride	0·16	0·15	0·03
	0·18	0·13	0·16
	0·19	0·15	0·12
Aqueous bromine	0·16	0·13	0·10
	0·15	0·11	0·15
	0·17	0·13	0·13
Alcoholic KOH	0·38	0·20*	0·31
	0·49	0·20*	0·42
	0·39	0·22*	0·28

* Fibre tended to slide abruptly during these measurements.

The results for sulphuryl chloride and bromine treatments agree in general with those of previous workers[1,2] using other techniques, and show that these reagents markedly reduce the directional coefficient of friction.

Treatment with alcoholic potash has caused no major reduction in the directional coefficient, which indicates that this reagent probably produces its unshrinkable effect in a manner different from the others. Further work is in progress on this subject.

I am indebted to Messrs. M. R. Freney and E. H. Mercer for helpful discussions, and to Miss P. Howard for assistance with the experimental work.

An Illusion of Size

I READ Dr. A. Loewenstein's letter[1] at the time of publication, and some of my colleagues and I repeated his experiment and, on the whole, confirmed his observations. Prof. H. Hartridge[2], however, appears to have experienced "An Illusion of Size" much greater than we could observe. I am quite at a loss to see how Prof. Hartridge obtained the measurements he quotes.

The nickel-brass threepences are made to a diameter across the flats of 0·823 in. or 21·082 mm.; from 1942 onwards the corners have been slightly rounded, so that the diameter over these is 0·860 in. or 21·844 mm. instead of the theoretical 21·872 mm. calculated for a dodecagon; earlier coins had nearly, but usually not quite, sharp corners.

These coins are struck from round blanks and are expanded into a dodecagonal steel collar in the coining press. A working tolerance of + 0·005 in. (0·077 mm.) is allowed in the dimensions of these collars, but this difference is, of course, far too small for visual observation.

It appears to me that the probable explanation of the 'illusion' is that the raised edge of the coin is not flat but considerably rounded, especially towards the edge of the coin, so that the reflexion of narrow-angle illumination appears as a bright line about half the width of the raised edge; the outside of this line would, in suitable conditions, be perceived as the edge of the coin, thus giving the illusion of smaller diameter.

When the coin is placed on a black surface, the reflexion from the extreme edge will be of that surface, and in suitable conditions would not be visible.

The edges of all coins become rounded in circulation, which may explain Dr. Loewenstein's observations on shillings.

Occurrence of Hexadecatrienoic Acid in the Glycerides of Rape (*Brassica napus* L.) Leaf

THE unsaturated acids of leaf lipids have been shown to consist of octadecatrienoic (linolenic) and octadecadienoic acid[1], together with traces of oleic and palmitoleic acid[2].

In the course of ester fractionation analyses of leaf glycerides, it was found that the C_{16} unsaturated methyl esters of rape had abnormally high iodine values (*c*. 190) as compared with 94·8 required for methyl palmitoleate.

Crystallization of the methyl esters from 15 volumes of methyl alcohol at − 15° C. and fractionation at 0·1 mm. through an efficient column yielded a fraction with sap. equiv. 264·0 and iodine value 225·9. Further concentration of the C_{16} polyethenoid fraction was achieved by systematic crystallization of the lithium salts of the acids (8·4 gm.) from acetone. The less saturated acids were removed by crystallization from 90 per cent acetone at 10° C. and then the lithium salt of hexadecatrienoic acid was precipitated from 95 per cent acetone at − 5° C. Under these conditions impurities of lower iodine value remained in solution. From this concentrate methyl esters were prepared which on distillation at 0·1 mm. yielded 4·4 gm. of esters (sap. equiv. 263·2, iodine value 271·9; theory for methyl hexadecatrienoate, sap. equiv. 264, iodine value 288·5).

Hydrogenation of the methyl esters in the presence of nickel formate at 230° C. yielded methyl palmitate (m.p. 29°, not depressed by admixture with genuine methyl palmitate).

Bromination of the acids in ether at − 10° C. yielded 72 per cent ether-insoluble bromides, m.p. 181° C. (per cent Br = 64·3, as compared with 64·5 per cent required for hexabromopalmitic acid).

Ester fractionation analysis showed the following composition for two samples of rape fatty acids from the lipids soluble in acetone at 0° C. The fatty acids comprised respectively 1·14 and 1·15 per cent of the total dry matter and 24·3 and 23·1 per cent of the total lipids.

	Saturated	Unsaturated		
	(mainly palmitic)	C_{14}	C_{16}	C_{18}
Weight per cent	16·0	0·7 (2·0 H)	11·3 (6·0 H)	72·0 (5·4 H)
	15·1	0·5 (2·0 H)	17·1 (6·0 H)	67·3 (5·2 H)

The value for the mean saturation of the C_{16} unsaturated acids has been calculated as 6·0, but this figure is only approximate, since small proportions of other less unsaturated acids may be present.

Apart from the inclusion of hexadecatrienoic acid, the fatty acid composition of rape glycerides is shown to be not dissimilar from that of forage grasses[2], which from investigations to be reported elsewhere do not contain significant proportions of this constituent.

Rate of Entrance of Ammonia into Muscle Fibres in Relation to Carbon Dioxide Tension

FROM previous considerations[1] the following Donnan relation may be expected to apply across the muscle fibre membrane:

$$k_1/k = [NH_4]_1/[NH_4]$$

where k_1 and k are the potassium concentrations within and without, and similarly for the ammonium ion.

In a communication some years ago[2], it was pointed out that with an external concentration of 1 mgm. of ammonia nitrogen per 100 ml. a ratio of about 2·1 was reached across the membrane when the external concentration was 30 m.eq. per litre, and the k_1/k value could be expected to be about 4·0 (the high external K was used to prevent K losses). The result was interpreted then as a probable damage to the membrane resulting from high internal ammonia concentrations.

Later investigations have brought to light some striking facts. First, if the external ammonia be decreased below 1 mgm. ammonia nitrogen per cent under the same conditions, the ammonia ratio increases more and more until it equals that of potassium. This would be in agreement with the view that high internal ammonia concentrations were in some way affecting the balance or the permeability of ions. In addition, when we came to measure the rate of passage of the ammonium ion as described in a previous communication[3], and using no carbon dioxide or bicarbonate but a little phosphate, we got no measurable rate of ammonia entrance over several hours at room temperature. We varied in turn the details of the experiments and obtained the same results. We then carried out experiments with 5 and 15 per cent carbon dioxide, maintaining the *p*H constant by substituting the required fraction of sodium chloride by sodium bicarbonate. A great difference resulted in the rate of ammonia entrance, and with 15 per cent carbon dioxide it exceeded that of potassium chloride (without the latter being appreciably affected). This was proved by direct analyses as well as by observing the volume change.

The experiments recall the interchange of potassium and ammonia in yeast which occurs only in the presence of carbon dioxide. (The effect of carbon dioxide was many times repeated and there appears no doubt about it. A few experiments by Fenn *et al.*[4] under different conditions would appear to indicate a different result, but these cannot be fully considered here.)

From such experiments it is clear that the undamaged muscle fibre membrane is either impermeable to the ammonium ion or is very slowly permeable, but that a great facilitation of entrance can be produced by carbon dioxide. Into ammonia equilibria or steady states across the muscle fibre membrane there enters a complexity quite absent from the simpler potassium, rubidium, chlorine, bromine, bicarbonate and hydrogen ion relationships.

The experiments of Fenn *et al.*[4] are open to question on several important points. For example, under their conditions it can be shown that numbers of fibres are losing their differential permeability for potassium and sodium throughout, and that this loss is irreversible, a very confusing complexity being established. It may also be noted that a misleading statement occurs in their paper to the effect that since potassium diffuses out slowly from isolated immersed muscle (in ordinary Ringer fluid) the ratio of potassium ions across the membrane can be made anything one pleases by changing the external K, and it has therefore no significance. If, by this, it is intended to convey that K ratios in general across the membrane have no significance, we do not see how such can be seriously maintained in view of the evidence already considered[1].

At and above the external maintenance K level, a definite K ratio is reached and maintained for long periods (48 hours in the cold). Such ratios are in full accord with the theoretical treatment of a membrane permeable to potassium ions and small anions, but not to sodium ions and larger anions of the type of sulphate, or phosphate esters. It must be taken now as proved that the muscle fibre membrane is of such a kind, unless we are prepared to entertain very fantastic hypotheses.

ROYAL SOCIETY OF CANADA

ANNUAL MEETING

THE meeting of the Royal Society of Canada for 1945 was held at Queen's University, Kingston, Ontario, during May 20–23, under the chairmanship of the president, Prof. J. K. Robertson, professor of physics at Queen's University. In the scientific sections, one hundred and four fellows, and half as many guests, were in attendance.

In addition to sectional and business meetings, there were two largely attended evening meetings. On the evening of May 21, the Society's medals were presented. Prof. R. B. Thomson, University of Toronto, received the Flavelle Medal as a tribute to his work on the comparative anatomy and physiology of plants. The Henry Marshal Tory Medal was presented to Dr. Otto Maass, professor of physical chemistry at McGill University, assistant to the president of the National Research Council, and director of chemical warfare and smoke for the Department of National Defence. He was hailed as a man possessed of experimental skill and scientific imagination, with a fondness for hazardous experiment, who has played a leading part in planning chemical research in Canada since the outbreak of the War. The Willet G. Miller Medal was given to Dr. M. E. Wilson, Geological Survey, Ottawa, who, conspicuous among Precambrian geologists of the world, has done much in Canada in the development of mining. The Lorne Pierce Medal was awarded to L'Abbé Felix Antoine Savard, Laval University, and the Tyrell Medal to Prof. F. Landon, University of Western Ontario.

After the presentation of medals, Prof. J. K. Robertson delivered his presidential address on "Continuity and Discontinuity". The paper was divided into two parts: a discussion of the progress of philosophical opinion down to the eighteenth century, followed by an assessment of the development of the two conceptions by physicists up to the present day. Recognizing that "present-day physics continues to demonstrate the inter-play of continuity and discontinuity", he concludes that "The modern physicist no longer accepts a materialistic philosophy and no longer assumes that, as time goes on, he will learn more and more about the ultimate details of a real objective world. His advances have shown him that measurements and observations can not give him exact knowledge beyond a certain stage, and hence for him, what is beyond has no meaning. His aim now is the more modest one of describing facts and observations in terms of correlating laws, which in the last analysis can be expressed accurately only by mathematical symbols".

On the evening of May 22, following a complimentary dinner given by the Mayor and City Council of Kingston, a popular lecture, "Biological Control of Insect and Plant Pests", was given by Dr. W. R. Thompson, Imperial Parasite Service, Belleville, Ontario. This paper so impressed the audience that a resolution was passed at a general meeting next day expressing to the Imperial Institute of Entomology its appreciation of the work done in Canada during the War, and asking that arrangements be made for its continuation.

In Section I, twenty-one papers were presented on subjects of historical or literary interest in French Canada.

In Section II, the presidential address by Prof. W. H. Alexander was a provocative discussion of some obvious incompatibilities of temperament as between the ideals of a genuine education and the spirit of the ultra-democratic State as suggested by Plato's "Apology to Socrates". Papers were read in the fields of literature, philosophy, history and the social sciences. Anthropology and archæology were represented by papers on "The Distribution of Rubbed Slate Instruments in Eastern Canada" by Dr. Douglas Leechman, and by the myth of "Bear Mother" by Dr. Marius Barbeau. A timely paper was presented by Prof. R. Flenley, "The Results of the Reformation in Germany".

In Section III, the most important feature of the meeting was a symposium on the dimensions of the galaxy. This subject was first treated very ably by Dr. Helen Sawyer Hogg from the point of view of the observations on globular clusters. Dr. C. S. Beals dealt with the obscuring matter between the stars and its influence on estimates of galactic dimensions. These papers led up to the presidential address by Dr. J. A. Pearce, of the Dominion Astrophysical Observatory, entitled "The Dimensions of the Galaxy as Derived from Studies of Galactic Rotation", in which he reviewed the history of the subject from the time of Herschel to the most recent estimates.

Thirty-five other papers were presented to this Section, ten by title. A notable series of ten chemical papers was presented by Prof. Paul-E. Gagnon, of Laval University, Quebec, ranging from the synthesis of amino-acids to the technology of charcoal, and exhibiting the great activity in chemistry at that institution. Prof. William Ure, of the University of British Columbia, described the mechanism of the 'flotation process' of concentrating ores, showing the necessity of a water-repellent layer on the surface of the mineral. Prof. J. K. Robertson, Queen's University, described the effect of high-frequency discharges in producing patterns in thin layers of metal placed in the discharge tube. Five meteorological papers were read by members of the staff of the Meteorological Service of Canada, including a new theory of the mechanism of the 'Chinook' wind (the warm dry wind which frequently descends the eastern slope of the Rocky Mountains in Alberta) by D. H. Smith and C. E. Thompson.

Nineteen papers were presented to Section IV. In the presidential address, Dr. J. S. DeLury gave an outline of a hypothesis to explain crustal movements. In his opinion, the earth's crust is strong to a depth of 450 miles or more. Liquid rock, known as magma, and as lava when it reaches the surface, is formed in shallow levels by frictional heat generated in crustal movements, and is not inherited from a primitive molten earth. These movements are due to failure in the crust caused by thermal contraction followed by a very protracted process of collapse.

Dr. A. W. Jolliffe presented evidence that, geologically, the north-western part of the Canadian Shield may be divided into four sub-provinces. From north to south these are: (1) Great Bear—characterized by Proterozoic formations, north-east faulting with right-hand displacements, and uranium–silver–cobalt–nickel–copper mineralization; (2) Yellowknife—characterized by Archæan formations, north to north-west faulting with left-hand displacements, and gold mineralization; (3) East Arm—characterized by chiefly Proterozoic formations, north-east faulting, and copper–cobalt–nickel–gold mineralization; and (4) Taltson—by both Proterozoic and Archæan formations, north to north-west faulting, and silver-lead-gold mineralization.

Dr. T. L. Tanton offered a theory, based on a study of conchilites and the work of W. D. Francis, suggesting the steps whereby non-living matter may have evolved into semi-living organisms, which provided the catalyser for the synthesis of protein and the conditions that induced the evolution of primeval forms of life. Dr. M. L. Keith described brucite deposits in the Rutherglen District, Ontario. Franco Rasetti reported the discovery of Middle Cambrian fossils in the Gaspé, the first recorded in the Province of Quebec. Dr. R. F. Legget described the geology of the "Shipshaw" area on the Saguenay River, and reported finding wood and other organic matter imbedded in the clay. Peter Ginn described an ultrabasic rock near Lochalsh, Ontario.

Dr. Robert Newton, president of Section V, in discussing the northern limits of wheat production, pointed out that wheat production in Canada is mainly confined to the southern plains region of the Prairie Provinces. Its possible northward extension concerns not only the potential world food supply, but also the feasibility of northern settlement. The longer summer days of northern latitudes are favourable to growth, but their value is reduced by association with lower temperatures. Rainfall is another important modifying factor. Moreover, the milling and baking quality of northern wheat is generally inferior. This may not destroy its usefulness as a local food resource, but makes it unsuitable as an article of commerce.

Prof. R. B. Thomson, who was awarded the Flavelle Medal, presented a paper entitled "Food Supply and Budding or Twinning Embryogeny". Prof. Thomson believes that the view that the asexual type of embryo initiation involved in budding or twinning embryogeny is due to recent mutation is not supported by sufficient evidence; whereas that for its being an innate or constitutional potentiality is satisfactory. The expression of this potentiality, however, is generally kept under control as indicated by the prevalence of simple embryogeny (one embryo from one zygote) in the main lines of evolutionary advance. Thus the problem of accounting for the sporadic occurrence of budding or twinning at different levels in such advance is concerned with the elimination of established control. This has been effected in animals by various physical and chemical experimental procedures. Up to the present, however, little attention has been given to the influence of food supply, and some experimental and other evidence, particularly the effect of excess nutrition on the production of a free nuclear stage in embryos normally undergoing simple embryogeny, indicates the importance of giving more attention to the possibly broader significance of this factor.

Dr. W. H. Cook, director of the Division of Applied Biology of the National Research Council, discussed some of the War research projects of the Council under the title "Some Wartime Food and Supply Problems". Under war conditions the main problem in feeding civilian or Service personnel is that of transport and distribution, complicated by the perishability of many foodstuffs. To meet the emergency, facilities had to be improvised to preserve the product, or alternatively the foodstuffs themselves had to be rendered less perishable. The dehydration of foodstuffs rich in proteins and fats was discussed in relation to the measurement and maintenance of quality and the type of deterioration that occurs. Several new chemicals required by war industry can be provided by the fermentation of starch. Reference was made to the bacterial fermentation yielding 2,3-butanediol, a material readily converted to butadiene and other chemicals.

Thirty-eight other papers on various phases of biological and medical sciences made up the programme of Section V. These included an important communication by Dr. B. P. Babkin, describing the interference of quinine bisulphate with cholinergic mechanisms in the heart and stomach of the dog, and a demonstration by Dr. C. C. Macklin that venule capacity in the lung is increased on inspiration.

Fifteen new fellows were presented, including the following in the Scientific Sections: Section III (Chemical, Mathematical and Physical Sciences): R. Brauer, E. W. Hewson, O. J. Walker; Section IV (Geological Sciences): V. J. Okulitch, J. E. Thomson, H. V. Warren; Section V (Biological Sciences): E. W. Crampton, J. Labarre, W. Leach, C. A. Mitchell, A. W. H. Needler, D. Y. Solandt.

Officers for 1945–46 were elected as follows: *President*, Prof. E. S. Moore, University of Toronto; *Vice-President*, Prof. H. A. Innis, University of Toronto; *President of Section I*, Dr. S. Marion, Ottawa; *President of Section II*, Prof. D. C. Harvey, Dalhousie University, Halifax; *President of Section III*, Prof. C. T. Sullivan, McGill University; *President of Section IV*, Dr. B. R. MacKay, Ottawa; *President of Section V*, Dr. B. P. Babkin, McGill University.

MODE OF ACTION OF PENICILLIN

SOME of the more recent work on the mode of action of penicillin was briefly reviewed in *Nature* (155, 403, March 31, 1945). Work noted there established the fact that penicillin is not merely bacteriostatic but also can actively destroy some micro-organisms. This bactericidal effect appears to be exerted especially upon the young bacterial cell and upon feeding bacteria, and to be therefore conditioned by certain factors in their environment. A leading article in the *Lancet* (276, March 3, 1945) summarizes the facts about this question which were available up to that date.

Important recent papers have since appeared. Thus E. Chain and E. S. Duthie (*Lancet*, 652, May 26, 1945) point out that Fleming, in his original paper on penicillin, recorded its slow bactericidal effect on *Staphylococcus* and its lytic effect under certain conditions. They explain that the original statement by the Oxford workers that penicillin is mainly bacteriostatic was based on the fact that it did not affect the oxygen uptake of resting *Staphylococcus*, for large numbers of viable colonies were found after incubation with penicillin in Ringer solution for twenty-four hours. They then review work done in the United States, which demonstrated that penicillin is bactericidal, but that it is not so under unfavourable conditions (such as low temperature or exhausted media) and that its bactericidal effect can be increased by substances which enhance bacterial growth and decreased by substances which interfere with bacterial growth (for example, sulphadiazine). From the results of their own work recorded in this paper, Chain and Duthie conclude that, during the resting phase of *Staphylococcus*, even large concentrations of penicillin have no effect on the oxygen uptake. During the early lag phase, however, and during the logarithmic phase of multiplication, penicillin has a strong inhibitory effect, and eventually completely stops the oxygen uptake, even in small concentrations (0·04–0·1 units per c.c.). They also demonstrated a strong bactericidal effect in the early lag phase and the logarithmic multiplication phase, but no measurable bactericidal effect during the resting phase. This confirms American work. Chain and Duthie conclude that penicillin can exert a bactericidal effect on *Staphylococcus* before actual division occurs, but that the organism can undergo at least one division in the presence of penicillin when it is added during the logarithmic phase of multiplication. It appears to interfere with some metabolic function of the early stages of bacterial development. Helvolic acid, the bacteriostatic antibiotic, antagonizes the bacteriostatic and bacteriolytic action of penicillin. Sulphanilamide and sulphamezathine, on the other hand, do not prevent the occurrence of several bacterial divisions and have no antagonistic effect on the bactericidal effect of penicillin on *Staphylococcus* and *Streptococcus*; on the contrary, they have a synergistic effect.

Chain and Duthie compare the modes of action of penicillin and the sulphonamides and review some of the literature upon this subject. They conclude that penicillin can kill *Staphylococcus* in the early lag phase before cell division has occurred, while sulphonamide kills only after several divisions have taken place in its presence. These results may be compared with those obtained by W. S. Miller, C. A. Green and H. Kitchen (*Nature*, **155**, 210, Feb. 17, 1945), who estimated the growth of the Oxford *Staphylococcus* turbimetrically in the presence of penicillin and sulphonamides and also discuss the effects of these two kinds of substance. They suggest that confusion may arise in discussions of bacteriostatic and bacteriolytic action because too fine a distinction is drawn between these two modes of action. Both penicillin and sulphonamides act by inhibiting cell multiplication; but, while sulphonamides inhibit the growth of almost every kind of cell as well as that of bacteria, there is little evidence that penicillin does this. Additional knowledge of the chemistry of penicillin may reveal that its mode of action is, like that of the sulphonamides, related to its chemical structure. It is unlikely that the mode of action of penicillin is unique; it is more likely that it differs from that of sulphonamides only in degree.

P. Bonét-Maury and R. Pérault (*Nature*, **155**, 701, June 9, 1945), using the differential photometer at the Radium Institute, Paris, suggest that, whereas the sulphonamide used by them (Dagenan 1162 F) does not stop but delays proliferation of *Staphylococcus aureus*, penicillin stops proliferation almost immediately, even at low concentrations, and that lysis follows. They found, however, that later a second proliferation occurred regularly, followed by a second partial lysis and then a second post-lytic growth. These results recall those obtained by J. W. Bigger (see *Nature*, **155**, 403, March 31, 1945). Bonét-Maury and Pérault obtained their results with six different penicillins (English, American and French). J. Hirsch (*C.R. Ann. Soc. Turque des Sci. Phys. et Nat.*, **12**; 1943–44) also studied the action of penicillin *in vitro* by manometric methods, and his work is discussed by Chain and Duthie (*loc. cit.* above). R. Knox (*Lancet*, 559, May 5, 1945) also concludes that the action of penicillin can be bacteriostatic, bacteriolytic or bactericidal, and that the young bacterial cell is particularly susceptible to penicillin. A. B. MacGregor and D. A. Long (*Nature*, **155**, 201, Feb. 17, 1945), studying the action of penicillin in relation to their work with penicillin pastilles (see *Nature*, 341, March 17, 1945), conclude that penicillin is bactericidal as well as bacteriostatic.

Very instructive also is the direct microscopical observation by Prof. A. D. Gardner (*Lancet*, 658, May 26, 1945), whose earlier work (*Nature*, **146**, 837; 1940) suggested that weak penicillin inhibited growth but did not prevent it, on the effects of penicillin on the spores of *B. anthracis* and *B. subtilis*. Gardner found that strong penicillin (50–100 units per c.c.) slowly kills the spores. Those of *B. anthracis* were more susceptible than those of *B. subtilis*, but neither were completely eliminated and there was no gross swelling. The spores gradually lost their high refractility and became empty ghosts. Weaker solutions of penicillin (0·1–1·0 units per c.c.) allowed the earliest phase of germination to occur, and the spores of *B. anthracis* then swelled up and became spherical coccoids which burst. Those of *B. subtilis* underwent similar changes, but all were not killed. Nevertheless, even the weakest inhibitory dose of penicillin renders the great majority of the spores non-viable. Spores studied in non-nutrient media were, however, little if at all affected, even by strong concentrations of penicillin, so that penicillin acts upon feeding bacteria and its action begins directly the bacteria begin to feed. Prof. Gardner concludes that the action of penicillin on sensitive species has little or no connexion with multiplication or division, although penicillin did cause abnormal divisions in sensitive *S. typhi* (long waists, spindle-shaped swellings, etc.). The majority of *Staphylococcus aureus* and *Streptococcus pyogenes* growing on agar are checked or killed before any visible growth or division has occurred. These conclusions, based upon direct microscopical examination, must carry great weight. It would seem that what is now required for a better understanding of the mode of action of penicillin is more exact knowledge of the chemistry of penicillin and the correlation of this, by the methods now being used for the biochemical analysis of micro-organisms, with the enzyme systems and other metabolic features of the organisms concerned.

G. LAPAGE.

RADIO WAVES FROM THE SUN

As the technique of radio-frequency measurement and application has progressed to successively higher frequencies, various investigators have from time to time turned their attention towards a demonstration of the interchangeability of thermal and radio methods of detecting electromagnetic waves. The use of normal radio receiving technique to detect thermal radiation from a hot body has always been an attractive line of experiment; and for this purpose, the sun, in spite of its great distance away from the earth, would appear to offer considerable advantages as a source of radiation of the desired type. The practicability of the reception and measurement of so-called 'cosmic noise' on an ordinary radio receiver has been demonstrated in various investigations, notably those described during 1932–39 by K. G. Jansky, who worked on frequencies of the order of 10–20 megacycles per second, and later (1940–44) by G. Reber, who described corresponding measurements made at frequencies of 160 Mc./s. In these cases, the investigators concluded that the radiation which they measured originated in interstellar space, and, from observations made of the direction of arrival, it was considered that the source of this cosmic noise was closely associated with the Milky Way. Both Jansky and Reber made attempts to observe any 'noise' radiation received from the sun, but although recently (*Astrophys. J.*, Nov. 1944) the latter investigator claims to have obtained definite evidence of this, the amount of such radiation received at the above frequencies is very small.

In a paper entitled "Microwave Radiation from the Sun" (*J. Franklin Inst.*, April 1945), G. C. Southworth describes some experiments conducted in the summer months of 1942 and 1943 in which a small but measurable amount of radiation from the sun was obtained with a conventional type of radio receiver operating on frequencies between 3,000 and 30,000 Mc./s. (wave-lengths between 1 and 10 cm.).

Following earlier work by Wien, Lord Rayleigh and Jeans, a complete formula for the energy distribution in the spectrum of a black-body radiation was derived by Planck from quantum considerations. At high temperatures and long wave-lengths, a condition of particular interest in the case of radio waves from the sun, the Planck relation reduces to the Rayleigh-Jeans formula. Applying this formula to the calculation of the energy distribution in the solar spectrum gives a result which is in general accord with experimental measurements throughout a considerable part of the visible and infra-red portions of the spectrum. The experimental results now described by Southworth tend to show that the same formula may be extended at least as far as the centimetre-wave portion of the radio spectrum.

These recent measurements were made at three wave-lengths between 1 and 10 cm. using an antenna within a parabolic reflector of high directivity and a suitable type of radio receiver. At the longest of the three wave-lengths the measurements of received power agreed to within about ± 5 per cent of that calculated by the Rayleigh-Jeans formula. At the intermediate wave-length the mean measured value was about 12 per cent below that calculated; while at the shortest wave-length, the mean observed level was approximately one-ninth of that calculated from the above formula. In no case was any marked diurnal variation observed such as occurs at infra-red wave-lengths, but at sunrise and sunset the received power varied more or less proportionally to the area of the sun's disk above the horizon; this transition period was passed through more slowly as the wave-length was reduced.

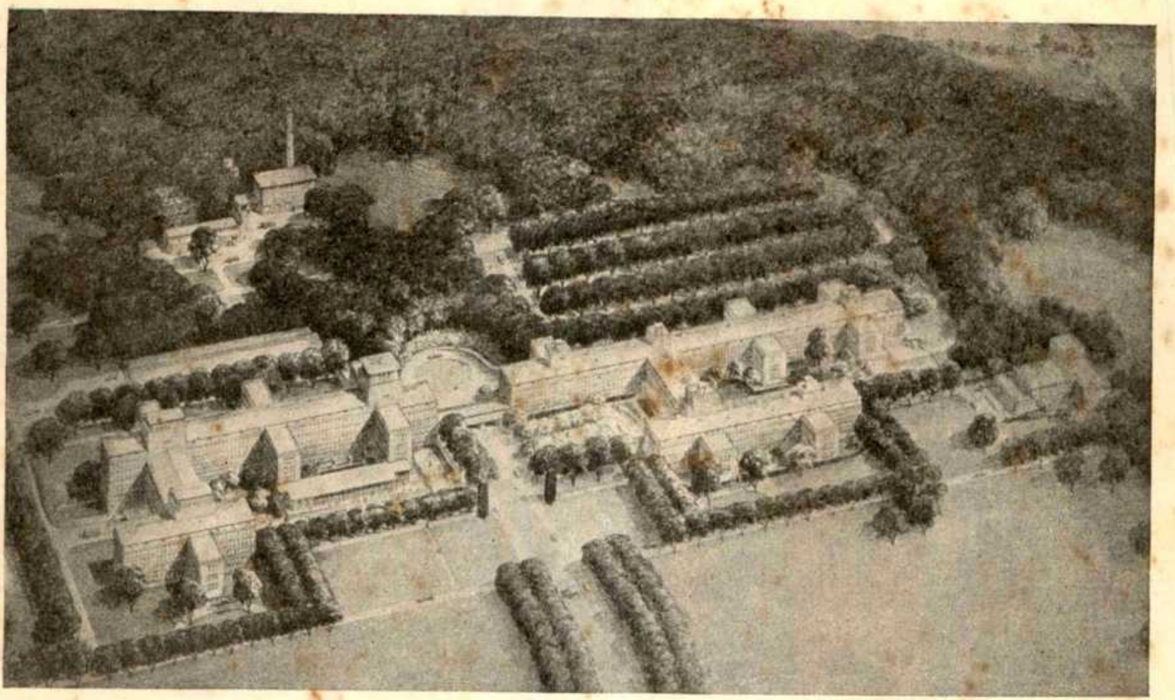
A particularly interesting part of the work described in Southworth's paper consisted of some directional measurements made by adjusting the receiver centrally on the sun and observing the decrease in output as the sun's disk moved out of the aperture of the receiving mirror. The effective angle of the latter, as measured by the displacement for which the received energy from a local source decreased to half the maximum value, varied from ± 3° for the longest to ± 0·3° for the shortest wave-length used in the experiments. In the measurements of solar radiation, the apparent aperture was much wider than this at the shortest wave-length, where it amounted to more than 0·8°, a result which is ascribed to the fact that the sun is an apparent disk and not a point source of radiation. At the lowest frequency, the angular diameter of the sun is small compared with the aperture angle of the receiver, but at the highest radio frequency used in this investigation, these two angles are comparable with one another. It may be expected that, to a first degree of approximation, the measured solar pattern will have a breadth equal to the sum of the aperture angle and the angular diameter of the sun. The fact that the observed directional pattern is even wider than this sum may be explained on the assumption that the angle of arrival of the waves from the sun varies rather rapidly over a considerable range; so that the sun appears to the receiver as a shimmering body the apparent diameter of which is considerably larger than the true diameter. This increase in apparent diameter may also account in part for the discrepancy between the measured and calculated energy levels already noted.

While carrying out the above work, it was found that the noise appearing in the output of the receiver was sensibly less when the receiver was pointed at the open sky above the horizon than when pointed at nearby objects or when it was located inside a room. The magnitude of this horizon effect for the longest wave used was of the order of 10^{-19} watts per sq. cm. for a band width of 1 Mc./sec. The corresponding energy measured from the sun was about five times as great. At the shortest wave-length used, this 'horizon' effect was barely measurable, while the energy received from the sun was about 5×10^{-18} watts per sq. cm. for the same band-width conditions. Numerous attempts were made to observe cosmic-noise coming from the general region of the Milky Way with the view of locating more precisely the source of the noise reported on by Jansky and Reber, but these attempts have so far proved unsuccessful on the higher frequencies used by Southworth. This experience tends to support Reber's view that cosmic radiation varies inversely as the frequency.

Perhaps the most interesting result of all this work is the establishment experimentally of a close relationship between black-body radiation and ordinary radio waves. Receiving from a source some 93 million miles away, it has been shown that the earth's atmosphere is fairly transparent to wave-lengths of the order of a centimetre, although there is evidence of absorption and scattering at the shortest wave-length at which observations were made. The next stage in the programme of investigation contemplated will incorporate the best ideas of both the radio engineer and the designer of astronomical equipment with the hope that additional accuracy will bring out features so far overlooked. Such observations on the transmission of radio waves through the earth's atmosphere from an outside source provide a means of investigating the structure of the atmosphere not previously available.

NEW BUILDINGS OF BELL TELEPHONE LABORATORIES

As soon as war restrictions permit, the facilities of Bell Telephone Laboratories at Murray Hill, N.J., will be greatly augmented, according to an announcement by Dr. Oliver E. Buckley, president of the Laboratories. The proposed addition is approximately the same size as the initial buildings, which were opened in 1941 and cost more than 2,000,000 dollars. The new building will extend the lines of the present one about five hundred feet in a



BELL TELEPHONE LABORATORIES AT MURRAY HILL, N.J. THE PRESENT BUILDINGS ARE ON THE RIGHT (SEE *Nature*, **151**, 674; 1943) AND THE PROPOSED BUILDINGS AT THE LEFT.

north-easterly direction. Old and new buildings will be joined by a bridge with a sheltered bus terminal beneath. The accompanying picture shows the architects' sketch of the complete building group with roadways and tree-shaded parking areas.

Since the present building was opened in the autumn of 1941, about one hundred groups from varied industries, Government departments, and some from abroad have come to study its new features. The unique requirement of a laboratory is that it must be designed for change. Prominent among new features which visitors come to see are the quickly movable partitions and the ease with which wires, cables and pipes may be installed or removed and yet concealed from view.

There are no permanent partitions in the buildings except those around the stair wells and elevator shafts. All others are built of easily movable metal panels. The outside surfaces of these units are sheet steel and they are separated by a 3-in. space which is packed with rock wool to prevent the transmission of sound and heat. Doors and transoms are made in one unit which can be interchanged with a partition in any part of the buildings. Along the outside wall of the buildings there is sheet steel wainscoting under the windows and up the piers between them. This is the same in appearance as the partition panels. The wainscoting is removable without special tools to give access to service pipes and wiring which are installed behind it. Similar wainscoting is applied around interior columns.

At intervals, small wings jut out from the main building providing well-lighted offices for physicists, chemists and engineers conveniently close to their laboratories. Shops, library, medical department and restaurant all fit into the pleasing functional pattern. The fields and woods, courtyards and shaded lawns all tend to make it a pleasant place in which to work.

People are all-important to an institution, the products of which are discovery, invention and design—creations of the intellect. In choosing this 200-acre site, the Bell Telephone Laboratories management sought a pleasant and healthful countryside in the midst of desirable home communities which spread over a wide area in towns along the Orange Mountain Range and the adjoining valleys. There is no intention of creating a Company community in the immediate vicinity of the buildings. Murray Hill is about twenty-five miles from the New York headquarters.

The executive offices of Bell Telephone Laboratories will continue to be at 463 West Street, New York City, and a majority of the employees will continue to work there. With the addition at Murray Hill, however, about two thousand employees will work at the new site compared with more than one thousand employed there during the War. This will include all the research work, and most of the work of apparatus development.

Though designed for peace-time use, the present new laboratory opened just as the United States was entering the War, and its new and adaptable space proved to be a great aid to Bell Laboratories' war service. Within its walls scores of war projects have been started, some small and completed quickly, others large and expanding from a room to whole sections of the building. The completion of the Murray Hill building project will find Bell Telephone Laboratories well equipped to design better and more economical telephone and radio equipment for the Bell Telephone System. It will also be ready and equipped to continue its record of achievement in developments for the U.S. Army and Navy as they may have need for its services in the future.

FORTHCOMING EVENTS

Saturday, September 1—Sunday, September 2

Scientific Film Association (at the Technical College, Huddersfield).—Conference on "The Film in Science".

Saturday, September 1

At 9.45 a.m.—Mr. W. F. Andrews: "The Film in Industry", 1: "Scientific Film Needs in Technical Training"; Mr. H. Richmond: "The Film in Industry", 2: "Film Strip in Technical Training"; at 2 p.m.—Mr. Derek Stewart: "The Film as an Instrument of Scientific Research"; at 7.30 p.m.—Mr. Frank Goodliffe: "Film Production".

Sunday, September 2

At 10.30 a.m.—"The Film in Medicine" (Film Show and Discussion); at 2.15 p.m.—Dr. W. T. Astbury, F.R.S.: "X-Ray Adventures among the Proteins and other Molecular Giants"; at 7.30 p.m.—Programme of New Scientific Films.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Mechanical Engineers for Oil Refineries (Ref. No. C. 2587.XA), Senior Research Engineers (Ref. No. C. 2622.XA), and Senior Mechanical Engineers for direction of work on the application of Fuels and Lubricants to I.C. and other Engines and to various types of Industrial Work (Ref. No. C. 2667.XA), for home and overseas service with large Industrial Organization—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (September 7).

Assistant (temporary) to the Chief Engineer—The Clerk to the Committee, County Mental Hospital, Winwick, Warrington (September 8).

Engineering Assistant—The Engineer, Portsmouth Water Company, 26 Commercial Road, Portsmouth (September 8).

Assistant in Zoology—The Secretary, The University, Aberdeen (September 10).

Women Education Officers (temporary) for Nigeria: (*a*) Four Graduates in Science (Physics, Chemistry or Biology) for Junior Classes in Secondary Schools, (*b*) Two Fully Qualified Domestic Science Specialists for administrative, inspecting, and some teaching duties—The Secretary (IER: CA), Ministry of Education, Belgrave Square, London, S.W.1, or The Secretary, Scottish Education Department, 10 Abercromby Place, Edinburgh, 3 (September 10).

First Civil Engineering Assistant in the County Water Engineer's Department—The County Clerk, Lanarkshire House, 191 Ingram Street, Glasgow, C.1 (September 14).

Lecturer in Chemistry at Gordon Memorial College, Khartoum—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting Ref. No. F. 4717.A (September 15).

Organic Chemist at Long Ashton Research Station—The Secretary and Registrar, The University, Bristol 8 (September 15).

Research Physicist (preferably with experimental knowledge of electric circuits), and a Biologist, to establish and work in a suitably equipped laboratory in London to study and develop sensory devices for the blind under the general guidance of its newly appointed Sensory Devices Committee—The Secretary, St. Dunstan's, 9 Park Crescent, London, W.1 (September 15).

Chair of Philosophy—The Dean, Faculty of Arts, Fouad I University, Cairo, Egypt (September 15).

Assistant in Mathematics—The Secretary, The University, Aberdeen (September 15).

Lecturer in Production Engineering to teach Workshop Technology to the standard of Higher National Certificate in Production Engineering in the Denbighshire Technical College—The Director of Education, Education Offices, Ruthin (September 15).

Head of the Department of Horticulture—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow (September 15).

Professor of Veterinary Surgery, Obstetrics and Animal Husbandry at the Veterinary College, Ballsbridge, Dublin—The Secretary, Civil Service Commission, 45 Upper O'Connell Street, Dublin (September 28).

Assistant Lecturer or Lecturer in (*a*) Philosophy, (*b*) Mathematics (Applied Mathematics: special qualifications in Atomic Physics essential), (*c*) Engineering, (*d*) Mining (with special qualifications in Coal Preparation)—The Registrar, University College of South Wales, Cathays Park, Cardiff (September 29).

Lecturer in the Department of Mathematics—The Secretary, Queen's University, Belfast (September 30).

Lecturer (Grade III) in the Department of Pure Mathematics—The Registrar, The University, Liverpool (September 30).

Mining Consultant to advise the Government of Tanganyika on all matters pertaining to mining development in that Territory—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting C.2738.A (October 1).

County Analyst and Official Agricultural Analyst—The Clerk to the County Council, County Hall, Maidstone (October 6).

Lecturer in Psychology in the Natal University College, Pietermaritzburg—The Secretary, Universities Bureau of the British Empire, c/o University College, Gower Street, London, W.C.1 (October 7).

Regius Chair of Natural History at Aberdeen University—The Private Secretary, Scottish Office, Fielden House, 10 Great College Street, London, S.W.1 (October 15).

Sir Dorabji Tata Reader in Pharmaceutical Chemistry—The Registrar, The University, Bombay, India (October 15).

Director of the College—The Secretary, Royal Technical College, Glasgow (October 20).

Chemist and Bacteriologist to the Barnsley Waterworks Department—The Waterworks Engineer and Manager, Town Hall, Barnsley, Yorks (October 30).

Deputy County Surveyor and Engineer—The Clerk to the County Council, County Hall, Wakefield, Yorks (October 31).

Instrument Makers, experienced, used to high-class Experimental Work, for the Royal Aircraft Establishment, Farnborough, Hants—The Exchange Manager, Ministry of Labour and National Service, High Street, Aldershot.

Experimental Engineer with marked ability in design and development of instrument mechanisms, by a Mechanical and Electrical Instruments Manufacturing Company in East Anglia—The Ministry of Labour and National Service, Appointments Office, Lloyds Bank Chambers, Hobson Street, Cambridge, quoting Ref. No. 216.

Director of the Scientific Instrument Manufacturers' Association of Great Britain—The Secretaries, Messrs. Binder, Hamlyn and Co., River Plate House, 12-13 South Place, London, E.C.2.

Chemist, with good general knowledge, capable of undertaking investigation of methods for handling and processing palm oil, fruit juices and other food products, for British West Africa—The Ministry of Labour and National Service, Appointments Department, Sardinia Street, Kingsway, London, W.C.2, quoting Ref. No. O.S. 1034.

Mechanical or Civil Engineers for Middle East to take charge of sections of extensive construction and erection contract (must have experience of construction of large process plants, oil refineries, or similar works)—The Ministry of Labour and National Service, Appointments Department, Sardinia Street, Kingsway, London, W.C.2, quoting No. O.S. 1050.

Assistant Tutor in Mathematics—The Secretary, University of London Institute of Education, 42 Portman Square, London, W.1.

Inspectors of Cotton Cultivation in the Sudan—The Ministry of Labour and National Service, Appointments Department, Sardinia Street, Kingsway, London, W.C.2, quoting Ref. No. O.S. 1028.

County Horticultural Secretary—The County Secretary, N.F.U., Farmers' Club, Worcester.

Assistant Teacher of Civil Engineering and associated Subjects—The Principal, Birmingham Central Technical College, Birmingham, 1.

Lecturer (full-time) in Metallurgy—The Principal, Borough Polytechnic, Borough Road, London, S.E.1.

Lecturer in Geography, qualified to undertake work to Degree standard—The Registrar, Municipal College, Portsmouth.

Lecturer in Electrical Engineering (should possess an Honours Degree or equivalent qualification in Electrical Engineering or Physics, with Radio), a Lecturer in Electrical Technology and Maintenance (should possess a Degree or equivalent qualification in Electrical Engineering), and an Instrument Mechanic, in the Rotherham College of Technology—The Director of Education, Education Offices, Rotherham.

Lecturer (graduate) in the Metallurgy Department, and an Assistant Lecturer in Engineering for Workshop Technology and Practice, in the Swansea Technical College—The Director of Education, Guildhall, Swansea.

Engineering Workshop Instructor and Steward in the Batley Technical College and School of Art—The Education Officer, Education Offices, Batley, Yorks.

Lecturer (man or woman) in Mathematics and Physics—The Principal, Training College, Castle View, Dudley.

NATURAL HISTORY MUSEUMS AND RESEARCH

IN recent discussions on the place of museums in the reconstruction of our national life, attention has, not unnaturally, been concentrated on their educational functions. Less prominence has been given to their importance as instruments of research. Nevertheless, there can be little doubt that the expenditure of public funds on museums is justified as much by their contributions to the advancement of knowledge as by their services in the diffusion of information. This is conspicuously the case with the great national museums concerned with the various branches of natural history, where the specimens exhibited in public galleries are only a small fraction of the material available. The vast collections accumulated in the natural history departments of the British Museum at South Kensington, for example, or the great herbaria at Kew and Edinburgh, are of little significance from the point of view of popular education ; yet they furnish an indispensable basis, without which all work on biological systematics in Great Britain would be gravely impeded if it did not become impossible.

It is unfortunately true that the fundamental importance of taxonomy (or systematics) is not fully realized by all biologists. At many British universities the courses of teaching in zoology and botany deal with the classification of animals and plants in a very summary and inadequate fashion, while the methods and conventions of systematics are altogether neglected. It is not uncommon to meet with young professional biologists engaged in teaching or research who have only the most hazy ideas on how to set about the identification of an unknown animal or plant, and who would be completely at a loss if required to draw up a description of a new species. On the other hand, the increasing attention now given to the bearings of biology on practical affairs is leading to a general appreciation of the need for precise determination of the systematic units concerned, and to constant appeals to systematists for help in making these determinations.

It may not be inopportune, therefore, to recapitulate some elementary considerations regarding the functions of museum collections in the service of systematic zoology and botany. These considerations are very familiar to all systematists, but are too often forgotten or misunderstood by those whose work lies in other fields of biological research.

In the first place, museums are essential as depositories for the preservation of type-specimens, that is to say, the original specimens on which descriptions of new species (or lesser systematic units) have been based. No matter how carefully such descriptions may have been drawn up, the advance of knowledge will sooner or later render them inadequate, and the definitive identification of the species can only be settled by a re-examination of the type-specimens. In our everyday measurements of weights and distances, we no longer appeal to comparisons with natural objects—the weight of a grain of corn, for example, or the measure of a quadrant of the earth's meridian—but to standard weights and measuring-rods preserved in the custody of government institutions. Similarly, the type-specimens are the final standards to which, in subsequent changes of nomenclature, the systematic names must adhere, and by reference to which in cases of dispute the original diagnoses must be expanded and amended.

This leads to another point of importance in the functions of natural history museums. The type-specimens contained in any of the national museums form only a small proportion of the collections stored in them. For example, in the natural history departments of the British Museum the total number of specimens is counted in millions, but the type-specimens cannot amount to more than a few thousands. The question is sometimes asked: "What is the use of amassing and constantly adding to these vast collections?" The answer to this is twofold.

In the first place, no matter how finely we may subdivide our systematic units—species, subspecies, varieties, forms, phases and so forth—the narrowest category will always include some range of variability. No individual animal or plant is ever completely and in all respects identical with any other. To define the limits of this variation, to discover its laws and to explore its correlations, long series of specimens are required, such as are only to be found in the larger museums, and it is there alone that such studies can be profitably pursued.

In the second place, the discovery of new forms, whether of specific or infra-specific categories, sooner or later necessitates a re-examination of the characters of the related forms already known. Every systematist knows that new species are constantly being discovered which differ from their nearest allies in respect of characters which previous workers have not thought it necessary to take into account. When this happens, a revision of the whole group, be it species or genus or family, must be undertaken. This revision and re-ordering of the forms that are supposed to be already 'known' is the most urgent task confronting systematists, and it is one that can only be profitably approached with the help of the large museums.

To sum up, a precise and detailed taxonomy is an indispensable foundation of all biological research; instruction in the elements of taxonomic practice should form part of the training of all biologists; the custody of the standards of this taxonomy is as much the business of the State as the custody of the standards of weights and measures; the maintenance of large collections carefully preserved and arranged and accessible to all qualified workers is essential if the study of taxonomy is to keep pace with the increasing demands made upon it by workers in other fields of biological science, both 'pure' and 'applied'. No one, nowadays, is likely to question the immense part which museums have to play in popular education or to grudge the expenditure of public funds required if they are adequately to discharge this function. At the same time, however, it is to be urged that the importance of the 'study collections' in the national museums for the future development of biology in Great Britain should not be lost sight of, and that the relatively small expenditure required for their accommodation, staffing and continued development should be given a high priority in the national provision for the support of scientific research.

METHOD IN SOCIAL STUDIES

Methodology of the Social Sciences

By Prof. Felix Kaufmann. Pp. ix+272. (London, New York and Toronto: Oxford University Press, 1944.) 20*s*. net.

PROF. F. KAUFMANN, formerly of Vienna and now at the New School of Social Research in New York, has long been concerned with problems of methodology. Here he attacks the most difficult of them, the methodology of the social sciences, though only in the second and shorter half of the book. In the first half he surveys the general problems of scientific method, because of his belief that its chief issues are broadly identical in the natural and the social sciences, the difference between them being merely one of degree. In the contrast between deductive reasoning and empirical procedure, around which he weaves his main argument, the author sees the key to "the solution of many apparently unrelated problems in natural and social science".

The book covers a great deal of ground, much of it familiar, and inevitably the argument is very condensed. Its central purpose is to demonstrate the meaning of methodology as an "autonomous discipline", the author having described in an earlier contribution its task as that of making explicit—"to collect, systematise and justify"—the general assumptions which in making empirical statements the man of science takes for granted. In the present work Prof. Kaufmann amplifies that statement and says that the task is to make explicit the theoretical laws implicit in social science and their interrelation with one another and with physical laws. Perhaps his position can be indicated most fairly by giving two central points in his own words: "Most methodological issues in social science are directly or indirectly concerned with some aspects of the relations between natural science and social science, particularly the extent to which the methods of the former are appropriate to the latter". But the "comparison of physical laws and social laws has been misled by erroneous preconceptions concerning the nature of the former. Physical laws have been contrasted as necessary or strict laws with mere rules or tendencies prevailing in the social field. But as soon as it is realized, first, that no synthetic proposition is necessarily valid, and, secondly, that many physical laws, among them the most general laws, are not strict (empirical) laws either, this contrast is seen to be of no fundamental methodological significance". Elsewhere the author grants that social laws are "less precise" than physical laws, but insists that the difference is one of degree, and that many "rather precise" predictions of events can be made in the social world.

This is a painstaking study, and the author's views are generally stated with moderation, but many of them are debatable. Perhaps three general criticisms may be more to the point. (1) The argument is not helped in a book which is meant to be an essay in clarification by the use of terms which are clumsy and obscure, such as 'introspectionism', 'dimensions of relationality', and so on. This is made worse by inadequate editing, which has often allowed a wrong use of ordinary words, such as 'confounded' for 'confused', etc. (2) The author endeavours to reduce the logical gap between methods in natural and social science, and generally his formal argument is plausible enough; but at times he strains it beyond the point where it could stand up to his own tests. That is often evident in his concrete illustrations. "Rather precise" is scarcely scientific, all the less so when to show the possibility of social prediction one has to come down to so naive a level in the scale of proof as to say that "we have a rather definite idea about what will happen to a letter that we mail or to a railway train for which we have purchased a ticket"; or has to reach out beyond any legitimate range so as to claim that the biological side of man is part of social science. (3) The whole elaborate argument does not in the end get beyond the old and hard problem, with its two distinct aspects. One is the logical use of the intellectual instrument, whichever the discipline; the other is the application of the knowledge thus acquired to the building up of generally valid propositions. Here we are faced with the awkward experience that the more systematic a social discipline or school has tried to be, by the somewhat forced use of exact methods, the more dogmatic have tended to be its conclusions, so that often method became identified with doctrine. The author mentions how the controversy about scientific method between the behaviourist and the psycho-analytical schools of psychology clearly showed that each party really wanted to justify not a general method but its particular theory.

Prof. Kaufmann himself says that in this field scientific results must be judged in the light of their success. The social sciences have been much favoured in England, yet the great scholars who have pioneered and led in this field have spent little time on discussions of methodology as such. The interest in methodology has been greater among French scholars, whose logical bent inclined them to seek for universal formal laws, and especially among German scholars, always in search of some metaphysical system; and more recently in America, where bent and facilities have led to heavy labours in the statistical field. In a sense, that intense specialization in the pursuit of the 'scientific' has delayed the synthesis which alone could illuminate the heart of the social problem. Social causation is a matter of an eternally varying interrelation of things; and understanding will come to us not through any set general method, but, as hitherto, through the sensible appraisal at any given time of the several sides of man's life in society.

DAVID MITRANY.

MORBID HISTOLOGY OF THE EYE

A Pathology of the Eye

By Eugene Wolff. Second edition. Pp. vii+285. (London: H. K. Lewis and Co., Ltd., 1944.) 42*s*. net.

THE study of ocular pathology occupies a somewhat anomalous position in general pathology. In contrast to the extensive knowledge on the comparative anatomy of the eye, there is little systematized information on comparative pathology. In human pathology, the position of this specialized study is likewise unsatisfactory. Clinical ophthalmology is probably the most exact of the medical disciplines, for the diseases of the interior of the eye are almost as readily amenable to direct inspection as those of the outer eye. The wealth of biomicroscopic and fundus studies is, however, poorly supported by histological findings. Eye disease rarely leads to death, so that the special eye institutions have only very occasional opportunities of post-mortem examination, while such eyes as are removed in life generally show extensive secondary complications which have led to the removal of the eye; the primary processes themselves are not often seen under the microscope.

For these and other reasons the literature on ocular pathology is sparse and contradictory. If, in addition, ocular pathology is taken in a wider sense to include the mechanism of the disease-processes of the eye, and not merely anatomical end results, an unsatisfactory state of affairs almost reaches exasperation. Any attempt at a systematization of ophthalmic pathology must therefore be regarded with gratitude by the reader and as a Sysiphean task by the author. There are few such studies in English; that by Collins and Mayou represented the most ambitious attempt, both in scope and in its search for an etiological basis for a mass of disconnected histological features. Its obsolete histological interpretations, and its somewhat forced classification, make that book no longer serviceable. Mr. Eugene Wolff brought out a less ambitious attempt some five or six years ago. His "Pathology of the Eye" was essentially an account of what is known of the morbid histology of the common clinical conditions. Its excellent illustrations supplemented a rather elementary text, but the whole constituted an adequate text-book on the morbid anatomy of the eye. It has filled a gap for the student and practitioner, and the second edition shows considerable expansion. The author has wisely curtailed much redundant clinical information that appeared in the first edition, thus making room for further details on morbid histology. There is, however, little in this volume on the wider aspects of pathology as distinct from morbid histology.

In spite of war conditions the high standard of production noticeable in the first edition has been maintained.

SOCIAL PSYCHIATRY

Man and his Fellowmen

Modern Chapters on Social Psychology. By Dr. Samuel Lowy. Pp. xiv+194. (London: Kegan Paul and Co., Ltd., 1944.) 15*s*. net.

THE author of this book is quite evidently better equipped for discerning the social-psychological problems of our times than he is for elaborating the solutions to those problems. Indeed, his suggested solutions, apart from certain valuable exceptions, are inspired by a pathetically child-like confidence in the omnicompetence of the State. He offers no grounds to support his implied contention that the State itself is immune from those psychological ills from which the people as a whole are suffering.

No one should, however, be deterred by this criticism from buying and reading the book. In such a complex field, to point out the problems accurately, and to lay down the solutions unerringly, would call for a superman, and such a stature Dr. Lowy would be the last to claim. But he has certainly produced a valuable, readable and acute discussion, covering a very wide range of topics, of the psychological factors which lie at the root of the troubles which disorganize, disintegrate and devitalize the social body. Though I have several reservations regarding the author's proposed remedies in detail, yet I emphatically agree with him that many of these troubles are remediable and, in principle, easily remediable. We are to-day needlessly squandering a vast amount of human spiritual energy, and the social psychologist can point the way to greatly enhanced human happiness, both for the individual and for the social group.

No one with knowledge of the facts will be likely to challenge the statement that the volume of psychological disability to-day is vastly in excess of the facilities which exist for dealing with it. Even in the mental hospitals, only a small proportion of patients suitable for psychological treatment can in fact receive such treatment. Non-institutionalized sufferers form a far larger proportion of the general population than is commonly suspected—indeed the proportion is so high that adequate therapeutic provision for them is beyond the realm of practical possibility. Prevention is always better than cure, but where the evil is widespread and increasing and cure is impossible, prevention becomes simply imperative. Dr. Lowy makes a very comprehensive survey of the field in which such preventive psychiatry should operate, and one can easily agree with him that this work is unlikely to be undertaken to an adequate extent without considerable encouragement and initiative on the part of the State. Perhaps the most immediate need is that for greatly increased popular enlightenment on the subject. This need not involve the danger, no doubt anticipated by some, that an increased interest in psychological aberrations will itself breed such aberrations, for there is a large accumulation of sober, simple, unsensational and scientifically authenticated facts which clamour for immediate application to the important business of living together efficiently and happily. There are encouraging signs of a growing demand for such popular psychological enlightenment, and it is important that this demand should be met by a form of instruction well conceived both as to method and to content.

A further edition of this book, which we may confidently expect, will provide an opportunity for the weeding out of several teutonisms which have escaped the reviser's eye. J. LEYCESTER KING.

EXPERIENCES OF A WOMAN FARMER

Four Years Harvest

By Frances Donaldson. Pp. 115+16 plates. (London : Faber and Faber, Ltd., 1945.) 7*s*. 6*d*. net.

SOME four years ago Mrs. Donaldson, tiring of town life, started farming. She had neither previous experience nor close association with the land; all the preparation she allowed herself was a six months course at the Moulton Agricultural Institute, Northampton. She did not even give herself the twelve months apprenticeship on somebody else's farm, usually recommended as the least costly way of gaining experience; she straightway purchased and stocked a Midland clay farm of 375 acres. At the end of the first year she wrote a book, "Approach to Farming", describing her experiences as a beginner; she also gave some talks for the B.B.C. and had some very direct things to say about the process and the announcers which a man would either not have noticed or not have mentioned. That part of her work was clearly successful, and her farming was satisfying enough to induce her to continue; now at the end of the fourth season she gives us another book in which she sets out quite frankly both her successes and her failures.

The human aspects of farming loom far more largely in the book than the technical problems, and Mrs. Donaldson not only knows her mind but also has a vivid way of expressing it. She was not at all impressed by the 'technicians': "I think there is no one so smug, so unreasonably conceited, so bigoted and so invulnerable . . . in order to strengthen his self-importance he is driven to obscure, to render exclusive and immeasurably difficult that which he knows". Nor are officials more pleasing in her sight, with one single exception who, "curiously enough, was a man of distinction, personality and brains". The filling up of forms, which under the present system of controls in Britain has become almost a new industry, invokes some scathing comment: "there is something peculiarly nasty about form filling. If you wish to apply for a few yards of piping to lay some water on to a field you have to fill in the same form as you would use if you wished to build a £100,000 factory". Yet at the end of the book Mrs. Donaldson advocates nationalization and more form filling, more control, which of course would mean more officials. If all this came about we should await with interest another book from Mrs. Donaldson setting out her further experiences with the very considerable clarity she commands.

The reader will have judged that the author is a lady of marked personality and will readily understand that, having selected a farm staff that she liked, found some good farming friends to advise her, and arrived at a system of farming that she liked, she is making a success of it. This is all to the good, for there is no doubt that an infusion of women into the agricultural community would strengthen it. For many years now there have been successful women farmers; but it is only in recent times that the general public has known much about them. But it should not be inferred from Mrs. Donaldson's book that farming can be successfully tackled by any woman after only six months training. She has been fortunate in her time of starting: it has been a period of rising prices and of considerable willingness on the part of members of the agricultural community to help each other, while the War Agricultural Committees have been in a position to undertake work requiring big implements such as combines and dryers, the advantage of which Mrs. Donaldson gracefully acknowledges. There was a similar favourable period in the War of 1914–18 and for a time afterwards. But then came the slump. Whether that will happen again no one can tell. Meanwhile any woman who thinks of taking up farming would do well to read Mrs. Donaldson's experiences, for she will learn from them about the wide range of difficulties, technical and human, with which she will be confronted, and of the ways in which they were overcome. E. JOHN RUSSELL.

Society of Chemical Industry

Annual Reports on the Progress of Applied Chemistry. Vol. 28, 1943. Pp. 517. (London: Society of Chemical Industry, 1944.) 20*s.*

THIS volume surveys progress under the following principal headings: chemical engineering, plant and machinery; fuel; gas, destructive distillation, tar, and tar products; mineral oils; intermediates and colouring matters; fibres, textiles, and cellulose; pulp and paper; acids, alkalis, salts, etc.; glass; ceramics, refractories, and cements; iron and steel; non-ferrous metals; electrochemical and electrometallurgical industries; fats, fatty oils, and detergents; plastics; resins, drying oils, varnishes, and paints; rubber; leather; soils and fertilizers; sugars and starches; the fermentation industries; foods; fine chemicals and medicinal substances; photographic materials and process; sanitation and water purification. F. Rumford concludes that the study of chemical plant design is being neglected, or at least under-publicized, in Great Britain. W. W. Goulston refers to the influence of the cargo aeroplane and the application of jet propulsion on the future production programme of the petroleum industry. J. Grant welcomes plans for the formation of a research association for the paper-making industry. P. Parrish and F. C. Snelling anticipate a large post-'armistice' demand for fertilizers and remark on the enthusiastic reception in Britain of National Growmore fertilizer. J. Woolman records the use of the electron microscope for investigating the structure of steel. J. Hofton points out that security needs may have given the impression that Great Britain is 'tailing along' behind the United States in developing the plastics industry. T. R. Dawson states that the search for rubber-bearing plants has added little to the prospect of supplies. B. M. Brown mentions the substitution by British brewers of part of the barley malt by unmalted oat flakes. N. Evers emphasizes the importance of recent expansion in the production of mepacrine (the substitute for quinine) and penicillin.

Science and the Idea of God

By William Ernest Hocking. (John Calvin McNair Lectures.) Pp. xi+124. (Chapel Hill, N.C.: University of North Carolina Press; London: Oxford University Press, 1944.) 9*s.* 6*d.* net.

IN *Nature* of May 1, 1943, there appeared a survey of an American manifesto on Education for Citizenship, in the course of which special attention was directed to the contribution of Prof. W. E. Hocking of Harvard. The theme of his choice was the role of philosophy in that branch of education. This seemed an odd choice until he made it clear that he regarded philosophy, not as a luxury subject with no bearing on the daily bread of education, but as the sum of men's working beliefs, implicit in "every editorial, every play, every sermon, every novel, almost every conversation". He united learned acquaintance with the great philosophers and determination to see things with his own eyes, and he struck out his own line.

Prof. Hocking's latest book takes us back at once to the "conflict between religion and science" which waged last century. The conflict seems to have subsided on terms of mutual toleration. The scientific man is apt to get on with his job on the understanding that God never interferes. Religion replies that this is "equivalent to tolerating a dead God": Prof. Hocking sharpens this issue by putting it in the form of a dilemma: (1) God must not interfere in scientific business; (2) God cannot be an inactive cipher in human affairs. He then takes the reader through a closely knit argument, designed to show that science and religion, though sharpening and then solving their contemporary dilemmas, are "brought into a fertile union in which the idea of God is enriched". The book is not, and could not be, easy reading; but it will make a stirring appeal to many a man of science.

Politics and Morals

By Benedetto Croce. Translated from the Italian by Salvatore J. Castiglione. Pp. v+204. (New York: Philosophical Library, Inc., 1945.) 3 dollars.

FROM the bibliography of Croce by Castellano (1936) it may be inferred that most of the essays here translated appeared in 1925 ("Elementi di Politica"), but that some of those added to the 1931 volume ("Etica e Politica") are included. Translator and publisher omit this and all other information.

Croce's writing is diffuse and his method rhetorical, but he has something valuable to say, and what he wrote after the first World War may be relevant to the aftermath of the second. History, for Croce, is a process of conflict between rival tendencies and aims in the course of which the human spirit creates itself and attains freedom. One aspect of this conflict is that between mere force or political power and moral ideals. Perhaps the most valuable point he makes is that political theories are always in the first place political programmes, and only in the second are they attempts to find a rational basis for them. Even so they generally suffer from fallacies of abstraction, imitating the abstractions of natural science without the technical justification these have in their own sphere. Recent efforts to label political theory 'sociology' do not alter the case. A. D. RITCHIE.

The Bates Method for Good Sight without Glasses

By Dr. William H. Bates. Pp. 160. (London: Faber and Faber, Ltd., 1944.) 10*s.* 6*d.* net.

THOSE who are at all interested in the subject of this book are probably very well acquainted already with Mr. Aldous Huxley's book "The Art of Seeing". One of Mr. Huxley's motives in writing that book was to repay "a debt of gratitude to the pioneer of visual education, the late Dr. W. H. Bates, and to his disciple, Mrs. M. D. Corbett", to whose skill as a teacher he owed the very heavy debt of improvement in his own vision when his case seemed hopeless. Mr. Huxley's general position, following Dr. Bates, is that the orthodox ophthalmologist has paid exclusive attention to one aspect of the complex process of seeing, the physiological, and has ignored the mind, which makes use of the eyes to see with. Unfortunately, Mr. Huxley is incapable of writing anything but a very clever book; a short and easy set of advice and suggestions would have been far more acceptable to many a reader.

The original edition of Dr. Bates' book was published more than twenty years ago. This new and revised edition omits unnecessary technical material, but includes all that is deemed necessary for a layman's use. Dr. Bates based his theory of course upon visual re-education, instead of mechanical aid in the form of glasses. The object of this brief notice is simply to pass on this information. No attempt is made to decide the issue "when doctors disagree".

SCIENCE IN THE U.S.S.R.*

GEOLOGY AND PALÆOBOTANY

By W. N. EDWARDS
British Museum (Natural History)

MUCH has already been written on the expansion of geological research and the development of mineral resources in the U.S.S.R. during the last quarter of a century, and the Seventeenth International Geological Congress held in Moscow in 1937 provided an opportunity for viewing some aspects of that work in the field and in the laboratory, while the sessions and the publications of the Congress summarized achievements to that date. In June of the present year some British geologists were invited to resume personal contact with Russian colleagues, and to learn something of their recent progress on the occasion of the 220th jubilee celebrations arranged by the Academy of Sciences of the U.S.S.R., only a few weeks after the cessation of hostilities in Europe.

Although activities during the past few years have been dominated by the necessity for prospecting for new deposits of various strategic minerals and for further developing previously known deposits, a great deal of incidental stratigraphical, palæontological and tectonic work has been accomplished. The end of the War therefore brings a rich harvest of important monographs and maps awaiting publication, while the release from the urgent necessity of dealing with practical demands means that now, as the veteran Academician V. A. Obruchev said at Moscow, "it is the theoretical problems that claim our closest attention".

The geological map of the whole of the Soviet Union on the scale of 1 : 5,000,000, edited by D. V. Nalivkin and published in 1937, was partly based on a series of regional manuscript maps on larger scales, and many of these maps have since been published. The Central Geological Prospecting Institute, directed by I. I. Gorsky, is now in process of issuing the sheets of a map again planned to cover the whole of the U.S.S.R., this time on a scale 1 : 1,000,000 ; European Russia is already completed, as well as considerable areas of central Asia. A new map of the Urals (in preparation) will endeavour to show stratigraphy, tectonics, useful minerals, drift and lithology on the same map. The only regions where geological surveying has not been carried out in any detail are certain areas of north-east Siberia, where the frozen terrain is exceedingly difficult; these regions will probably be left until last in the programme for mapping geologically the whole of the U.S.S.R., but are by no means being neglected in the meantime, for a special Institute for the Study of Permanently Frozen Ground has been set up by the Academy of Sciences under the direction of V. A. Obruchev, with headquarters in Moscow and field stations at Igarka and Yakutsk.

Among publications of the past decade, pride of place should be given to the several different series of volumes planned to cover all aspects of geological science for the whole of the Soviet Union. "The Geology of the U.S.S.R.", edited by J. S. Edelstein, is arranged on a regional basis and will extend to twenty-seven volumes, of which six have appeared so far, on the Urals, Donetz Basin, Kuznetzk Basin, Transcaucasia (two) and Eastern Kazakstan. "The Stratigraphy of the U.S.S.R.", of which volume 1 on the Pre-Cambrian appeared in 1939, will be completed in fifteen volumes. In addition to "The Palæontology of the U.S.S.R." and the "Monographs of Palæontology", there is an "Atlas of the Leading Forms of the Fossil Faunas of the U.S.S.R.", of which some four or five volumes have appeared and another half-dozen are ready for publication. There are also series on the "Minerals", the "Petrography", the "Pegmatites", and the "Soils of the U.S.S.R.", "The Mineralogy of the Urals", and Obruchev's "Geology of Siberia" in three volumes. Six volumes of the Proceedings of the Seventeenth International Geological Congress were issued in 1939 and 1940.

Soviet geology has suffered the loss by death of three of its most distinguished leaders during the last year : A. A. Borissiak (1872–1944), who after an early career in stratigraphy and tectonics became the leading vertebrate palæontologist in the country, V. I. Vernadsky, the veteran mineralogist (see *Nature*, March 10, 1945), and A. E. Fersman (see *Nature*, July 7).

In palæobotany, much important work has been done recently on the floras of successive horizons in the upper Carboniferous and Permian of the Asiatic parts of the Soviet Union. A question which has interested palæobotanists for nearly half a century is the supposed occurrence of elements of the southern hemisphere *Glossopteris* flora in Siberia. *Glossopteris* itself was first reported, but not figured, by Amalitzky, who was not a botanist. Since then a number of other *Glossopteris*- and *Gangamopteris*-like forms have been described by Zalessky and others; but many palæobotanists outside the U.S.S.R. have long felt dubious about the value of these records. The whole problem still awaits detailed examination, but recent and still largely unpublished work by Maria Neuburg, who kindly showed me some of the material on which her conclusions were based, proves that some at least of the supposed glossopterids are absolutely distinct.

A promising discovery of a rich upper Triassic deposit of plants with well-preserved cuticles has been announced by Prinada, and S. N. Naumóva has ready for publication an extensive monograph on the spore- and pollen-content of strata of various geological horizons. The detailed description of Upper Cretaceous and Tertiary fossil plant assemblages and the delimitation of past floral provinces is being continued by A. N. Kryshtofovich and others. Kryshtofovich has recently published, as one of the volumes in the "Palæontology of the U.S.S.R.", a complete index of the fossil flora, which includes every reference to fossil plants of all ages from all parts of the Soviet Union ; with the vast increase in the literature of the subject such works are absolutely indispensable.

Two very able young palæobotanists lost their lives on active service during the War : K. K. Shaparenko, who had written on *Ginkgo* and on *Liriodendron*, and A. V. Yarmolenko, noted for his work on upper Cretaceous plants and particularly on fossil woods.

The flexibility in the organization of scientific research in the Soviet Union, leading frequently to the combination of previously separate bodies or journals,

---

* Continued from page 259.

and the habit of changing the names of institutions, is apt to be confusing to outsiders. The Academy of Sciences presented all those who attended the Jubilee Celebrations with a finely produced volume of more than three hundred pages which describes in detail all the sections and institutes of the Academy itself; this is a most useful and up-to-date work of reference but is not, of course, all-embracing. The compilation of a directory of all scientific institutions, giving not only their present but also their previous names, addresses, functions and publications, would be an inestimable boon.

PHYSICAL CHEMISTRY

By PROF. C. N. HINSHELWOOD, F.R.S.
University of Oxford

A VISIT to the scientific institutes of Moscow and Leningrad leaves one with several vivid impressions. Perhaps the strongest is that of a numerous and enthusiastic community of scientific workers, led by the most eminent scholars of the country, housed in excellent buildings, well equipped with all the facilities necessary for their work, and enjoying a nation-wide prestige which must be almost unprecedented in the history of learning.

The institutes have passed through a period of great difficulty, having been uprooted by war and evacuated to other parts of the country: as one of the directors remarked, "Two evacuations are about the equivalent of one earthquake". Nevertheless, the return to normality has gone on with remarkable speed: and new institutes seem to arise in the course of a few months. On the outskirts of Moscow, overlooking the river, and adjoining what will presently be a splendid park, stand the laboratories of Academician Kapitza and of Academician Semenov. The latter laboratory has been converted from a very fine old house and has been entirely refitted in a very short space of time to accommodate work which is now being permanently transferred from Leningrad to Moscow. The appreciation of the fact that scientific work flourishes best in serene and agreeable surroundings seems to be general. The psychology is sound, and we must hope that a similar understanding will be shown by those responsible for establishing new research centres in Britain.

It was also interesting to observe that, despite the exigencies of war, there had been a general realization of the importance of maintaining long-range fundamental research; indeed, while admiring the breadth of view which seemed to have been shown by those directing the general policy, one wondered a little uneasily whether too much of the future in our own country might not have been sacrificed to immediate needs.

Various members of the Academy of Sciences discussed quite frankly with their visitors certain aspects of their present arrangements which they have found not quite satisfactory and which they are in process of modifying. There is, for example, a feeling that in the past the organization of the work in laboratories was rather too centralized, and that for the best results rather more decentralization is beneficial. Another aspect of the same thing is that the great institutes have tended rather to overshadow the universities in research, and that the position of the latter will probably need strengthening. On the other hand, students from the universities actually do part of their work in the research institutes, so that a measure of valuable co-operation comes about. One can scarcely expect that in a vast and rapidly evolving country like the Soviet Union any of the forms of society have yet reached their stable level; but it is most gratifying to feel that in scientific matters the future seems, so far as can be judged, to be largely in the hands of the best men of science themselves.

It is only possible to mention specifically a few of the institutes and laboratories in which physico-chemical work is in progress. In Moscow there is the Institute of Academician Frumkin, which deals with problems of colloid science, taking the expression in the widest sense, which includes the study of adsorption, catalysis and electrokinetic phenomena. Beautiful experiments on the motions of charged mercury droplets in different solutions were demonstrated by Frumkin himself and discussed in a lecture during the anniversary celebrations of the Academy last June. In Moscow also are two new institutes, one presided over by P. Kapitza, known as the Institute for Physical Problems, and the other the Institute of Physical Chemistry, presided over by N. Semenov (whose name, English chemists should know, is pronounced Semyónov). The work of the former deals largely with low-temperature phenomena, and although much of it, especially the brilliant investigations on the properties of liquid helium, is of the greatest interest to physical chemists, it is perhaps best dealt with under the heading of physics. The Institute of Academician Semenov, recently transferred from Leningrad, houses a school of workers who, under the inspiration of their chief, have made one of the most characteristic of the Russian contributions to modern physical chemistry, namely, the intensive study in all their aspects of the phenomena of flame, combustion and explosions. The work of Semenov on the theory of branching reaction chains and the interpretation of explosion limits, thermal and non-thermal explosions, degenerate explosions and so on, is too well known to need description. Some of the more recent work has included ingenious studies of the way in which chemical reactions may be initiated upon a solid surface and propagate themselves into the whole volume of the material. Another development is the study of the surface electrical conductivity as a means of investigating films in which catalytic reactions occur. Much interesting work is being carried out on the part played by hydrogen atoms and hydroxyl radicals in reactions (some of this work in the Semenov Institute, some in the Frumkin Institute). It would be extremely difficult in a short account to mention individual workers; but perhaps I might remark how illuminating I found the contributions of Zeldovitch on the fascinating but extremely difficult problem of the rate of propagation of flame through combustible mixtures. This subject is of the greatest practical importance and of considerable theoretical interest, and the recent contributions maintain the traditions of the Semenov school.

It is not surprising at the present time to find much work of a physico-chemical nature going on in the Organic Chemical Institute in Moscow, especially in the high-pressure laboratory and in the sections dealing with catalytic reactions (Balandin and others).

In Leningrad it is hard to say whether the great Physico-Technical Institute, of which the head is

Academician Joffe, is of greater concern to physicists or to physical chemists. A great variety of problems are under investigation and many of them with a view to their ultimate practical application, but without any sacrifice of the fundamental scientific approach. Among the most important are: (1) the study of the remarkable properties of the thallium sulphide photo-cell, (2) the study of fibres and high polymers, and (3) a very intensive investigation of the properties of that important class of substances known as semi-conductors. In talks with some of his guests last June, Joffe explained some very liberal-minded views on the organization of research. While explaining that science was carried on for the benefit of the community, he expressed ideas on the practical realization of its aims from which the most individualistic would have had little cause to dissent.

In all the various institutes there is a lively appreciation of most of the problems which have occupied English-speaking countries of late years, and characteristic contributions are being made to most of them: kinetics and the transition state theory (Syrkin, Roginsky, Temkin and many others), photochemistry (Terenin, Kondratiev), and so on.

To watch the evolution of this great consciously directed effort will be of extraordinary interest in the next few years. In this connexion another matter arises. The knowledge of English is very widespread among our Russian colleagues. Is it not high time that we began to provide the corresponding advantage for our own younger generation of scientific men?

SURFACE CHEMISTRY

By Prof. N. K. ADAM, F.R.S.
University College, Southampton

DURING the recent celebrations of the 220th anniversary of the foundation of the Academy of Sciences of the U.S.S.R., I had the opportunity of seeing something of the very extensive and thorough researches which are in progress in surface chemistry in that country. Naturally, most of this work is being done in the Institute for Colloid and Electrochemistry, in Moscow, which is directed by Academician A. N. Frumkin; but some work on surface phenomena is going on elsewhere also.

Two lines of work appeared of exceptional interest on account of their novelty and their potentialities for extension and for practical application; these are the investigation of the promoting effect of small amounts of adsorbed gases on the catalytic power of metals, by S. Z. Roginsky and others, and of the influence of films adsorbed in the sub-microscopic cracks in solid surfaces on the tensile strength and hardness of solids, by P. A. Rehbinder and his team. Roginsky[1] finds that, as a rule, really clean metallic surfaces of platinum, nickel or tungsten have little or no catalytic power; but if a small quantity of oxygen, hydrogen or nitrogen is adsorbed on the surface, they become excellent catalysts for such reactions as the hydrogenation of ethylene. The adsorption of larger amounts of gas reduces the catalytic power, which finally diminishes to zero again when a large quantity of gas has been adsorbed. The maximum catalytic power is attained at a quite sharply defined concentration of gas adsorbed on the surface; when the amount of gas adsorbed is half, or double, that required for maximum catalytic power, the rate of the reaction is often only one fifth to one tenth of the maximum, sometimes even less. It is claimed that these catalytically active adsorbed layers, or patches covered by adsorbed layers, are remarkably stable and persist for some considerable time during which the catalysed reaction is taking place.

Rehbinder[2] has shown that such adsorbable substances as long-chain fatty acids very greatly increase the facility of slip in the glide planes of monocrystalline wires of metals, even when these are as thick as one millimetre; and also decrease greatly the tensile strength and hardness of such solids as mica, particularly when the solids are being deformed by stress. This is due to the penetration of the 'Griffith' micro-cracks found in the surface of all solids by adsorbed films, wedging open these cracks and consequently weakening the solid; and, one is tempted to suggest, possibly lubricating the slipping of one layer of the solid over another. This phenomenon may prove to be of importance in connexion with the use of fatty acids and similar substances for lubricating purposes.

One very interesting consequence of this adsorption in micro-cracks is shown when a polarizing electric potential is applied to a solid immersed in a solution of an electrolyte[3]. At that polarizing potential at which the electric charge on the solid becomes zero, there is no adsorption of ions on the solid surface from the electrolytic solution, and consequently no diminution of hardness of the solid. As the potential departs from this value, either positively or negatively, so does the concentration of adsorbed ions increase, with a consequent decrease in hardness of the metal. In fact, the curve showing the dependence of the hardness on the polarizing potential has a roughly parabolic form with a maximum hardness at the 'null' potential, in exactly the same way as the electrocapillary curve of mercury in solutions of electrolytes shows a maximum of interfacial tension. The maximum of hardness is found to be influenced by the presence of ions with high specific adsorbabilities, or by neutral organic substances, in a way very similar to that in which such substances affect the electrocapillary curve. Thus something closely similar to the electrocapillary effect can now be studied with solids. In one case at least, tellurium[4], it is said that the maximum of hardness occurs at a *positive* value of the polarizing potential, an unusual sign for the potential at the maximum.

Extensive studies on the viscosity and other mechanical properties of monolayers on water[5] as well as their influence on the stability of bubbles[6] are in progress, the results confirming and extending earlier work: A. A. Trapeznikov is also studying the effect of temperature on the spreading pressure of solids on water in very great detail[7], finding new phenomena which he claims are due to the hydration or entry of water into the solid or liquid fatty substances which spread, in the bulk phase as well as in the monolayers. V. Levich, in a mathematical investigation[8], concludes that the damping of ripples by surface films can be ascribed to their low compressibility.

B. Derjaguin is continuing a long research[9] on the distance to which the influence of a solid surface extends into liquids in contact with the solid, using a variety of methods. These include measurement of the thickness of layers of liquid remaining under definite conditions of draining, between an air bubble and a glass plate against which it is pressed, or between two air bubbles; in other experiments the thickness of liquid remaining on a glass plate, or in a wedge-shaped slit, when a strong current of air blows most of the liquid away, is measured. Optical interference methods are used; and although complex hydrodynamical effects are clearly involved, there seems good evidence that some degree of structure, with considerable anomalous viscosity, persists far into the liquid in such cases as solutions of aluminium naphthenate, and perhaps other long-chain substances, in mineral oils. The effect may perhaps extend as far as half a micron into the liquid. This work also may be of importance in the theory of lubrication.

A. Schuchowitzky has applied statistical methods to adsorbed layers at the surface of solutions[10], and A. B. Taubman[11] draws deductions from surface tension – concentration curves as to the orientation of many organic substances dissolved in water, including heterocyclic compounds, at the air – water surface.

S. Roginsky is attempting to develop a general theory of the conditions for activation of heterogeneous catalysts[12]. At present, this appears to be couched in somewhat generalized terms, but one important point is the claim that the 'degree of supersaturation', a term used for the decrease of free energy, or extent of departure from equilibrium conditions, in the reaction by which the catalyst is formed, is a prime factor in determining its catalytic activity. This supersaturation is measured, in the case of a catalyst such as nickel oxide formed by dissociation of nickel carbonate, by the expression $RT \log_e p_e/p$, where p_e is the equilibrium dissociation pressure of carbon dioxide (or other gas given off during the dissociation) and p the actual pressure prevailing in the atmosphere above the dissociating solid when the catalyst is formed; T is the absolute temperature at which the catalyst is formed. It would appear possible that the reason why this so-called 'supersaturation' of the dissociation, leading to the formation of the catalyst, is important is simply that, if the pressure during formation is very much lower than the equilibrium pressure, the catalyst is formed very rapidly, so that its atoms are arranged in an irregular manner and cannot easily re-arrange themselves to a more stable, and less catalytically active, structure.

Finally, despite the heavy duties of direction of a very large and active institute, its leader, A. N. Frumkin, is continuing active research in a number of different directions[13], with many collaborators. These include work on the amount of oxygen which must be adsorbed on pure iron to confer passivity; continuation of work on the capacity, and general theory, of the electrical double layer; on the oxidative properties of charcoal leading to the formation of hydrogen peroxide; on overpotential, wetting and swelling of graphite, electrokinetic behaviour of activated charcoal and of mercury droplets in aqueous solutions. At one of the scientific meetings of the Congress he delighted the audience with a cinematographic record of the motion of mercury drops falling at right angles to the field between two electrodes; at first these are attracted to the anode, but as they approach this closely, their surface becomes so heavily oxidized that their charge changes sign and they are repelled.

In other institutes I saw work on the rounding off of rock-salt crystals at high temperatures, under the action of surface tension; and ingenious methods for measuring the concentration of free hydrogen atoms or hydroxyl radicals in burning gases (Semenov). A long, thin glass capillary, coated on the outside with a catalyst which produces rapid recombination of the free atoms or radicals on the surface, with a thermocouple inside, measures the heat produced by this re-combination, and from this the concentration of atoms or radicals is deduced. Allowance can easily be made for the heat produced by the burning gases by inserting a second, similar capillary containing a thermocouple but without any catalyst on the outside, close to the first.

The research institutes organized to study some particular branch of science are well, indeed almost lavishly, equipped and staffed; and although the primary object of these institutes is pure scientific research, the necessary liaison with all departments of industry appears good enough to enable scientific discovery to be put into industrial operation in any direction and on any scale desired, with a minimum of delay. The policy of the Soviet Government—to support scientific research on a very generous scale, for its own sake as well as for its actual or potential technical applications—appears thoroughly sound, as a long-range policy for a co-operative society.

The Russians claim to plan their scientific research, but one sees little sign of any restriction of individual initiative; individual scientific workers of proved ability or promise appear to have a very free hand in their choice of fields of research; and they are encouraged and expected to continue in a line of work for a very long time indeed, perhaps for five or ten years or even more. The contrast with so many industrial and even Government research establishments in Britain, where fundamental scientific research is so often relegated to a very low priority, and even if attempted is under continual threat of suppression or interruption after a few months or less because of the danger that it will not be immediately remunerative to the particular industry or department which undertakes the research, is somewhat disquieting to those who have the ultimate interests of British technical efficiency as a whole at heart. Naturally, the enthusiasm and the scientific 'morale', as well as the friendliness, of the workers in the Russian scientific institutes, is at a very high level, and was a real pleasure to see.

(To be continued.)

POST-WAR FOREST POLICY IN INDIA

By Prof. E. P. STEBBING
University of Edinburgh

EIGHTY years have passed since the Indian Forest Service was inaugurated under the auspices of Sir Charles Wood, Secretary of State for India, Lord Elgin, Governor-General of India, and Mr. (later Sir Dietrich) Brandis, its first Inspector-General of Forests. It was the first forest service in the British Empire and Dominions, and the first attempt by the British Government to introduce a correct forestry administration into a country over which it ruled. Various factors, including the steady recruitment of its gazetted service from home and the high standard of training demanded by the India Office for its forest probationers, have gone to produce the forest service and the great forest estate it controlled up to the outbreak of the War of 1914–18. Perhaps one of the chief causes, accounting for the steady progress in achievement for the well-being of the forests and the people, so large a proportion of whom are dependent in many ways on efficient forest management, has been the presence of an Inspector-General of Forests as adviser to the Central Government without intermission down through this long term of years. Many a period of storm and stress, as one looks back, threatening one or more forest regions in different parts of India, were safely negotiated through the presence at the ear of the Central Government of a cool and far-seeing forestry administrator who, with his great experience, could weigh impartially the pros and cons of any policy suggested by a local administration, and advise accordingly.

It was not until 1894 that the aims which had influenced the work of the Forest Department were voiced in Circular No. 22F. "A Note on 'Post-War Forest Policy for India'" was written last year by Sir Herbert Howard, Inspector-General of Forests (Manager, Government Press, New Delhi, 1944). The Inspector-General thus summarizes the principles embodied in this memorandum: (*a*) First and foremost, the preservation of the climatic and physical conditions of the country come before all other objects. (*b*) The preservation of the minimum amount of forest necessary for the well-being of the country is second only to (*a*) above. (*c*) Agriculture and cultivation come before forestry in the use of the soil. (*d*) The satisfaction of the requirements of the local population, given either free or at competitive rates, comes before revenue. (*e*) With the above objects fully provided for, the realization from the forest area of revenue to the greatest amount which efficient management permits.

If the order of the above objects of a correct forest management in a country is examined, it will be observed that after thirty years of forestry administration in the different parts of India, the Central Government and its adviser had fully appreciated that the chief role of the forest—Nature's forest which had not been grown by man—in a countryside was not the provision of revenue, and that the maintenance of an adequate forest staff should not be dependent upon the amount of revenue which came from the forests; that, in other words, the *raison d'être* of the forests of a region might fulfil far greater and more important objects than the mere provision of money. It would be incorrect to say that the excellent rules laid down in this circular were carried out to the letter all over India. There were serious back-slidings. But the present great forest estate of the country is witness to the fine work achieved, and that, to a considerable extent, the value of the forests and of the work is appreciated by the people.

Although more could not be expected at the time, the Circular of 1894 only related to the forests under the control of the forest service, that is, the reserved forests placed under a regulated management based on a sustained yield. This meant that private forests, as also the considerable forest areas under the Indian States, remained outside all Government forest supervision, though during the present century some of the Indian States had begun to recruit Indians trained in the forestry schools of Britain.

Howard's note is written for British India, but much of it has equal application to the Indian States. It is divided into two parts: Part 1, a review of present conditions, and Part 2, the Inspector-General's suggestions for the future. These are both considered under (1) the Government in relation to forestry; (2) existing forest policy; (3) existing demands on and supplies of forest resources; (4) floods, erosion and desiccation; (5) forest research; (6) forest education; (7) creation of a federal forest service; and (8) minor forest produce. From the point of view of general forest policy, it is the first four of these that are of primary importance, the others, important as they are, being more for internal consideration. It will be necessary here to confine ourselves to Howard's suggestions in Part 2.

Under the minimum forest area necessary for the well-being of a country—a subject probably now of the first importance to almost every highly populated country on the globe—Howard shows that the area of forest under Government control comprises only 14 per cent of the area of British India. Certain provinces, such as Assam, have large areas of the so-called State unclassed forests, which are not under professional forest management; but for India as a whole the forests are badly distributed. Except for the Central Provinces, Bombay and Madras, roughly speaking, south of a line from the Gulf of Cambay to Calcutta the forests under the Indian Forest Service consist of those along the foothills of the Himalaya, a narrow band only, the Assam forests and the Sundarbans, south of Calcutta, and smaller areas on the banks of the Indus, in the south of the United Provinces and in Bihar and Orissa. Reliable figures for the privately owned forests do not exist; but it is doubted whether the total including the Government forests would exceed 20 per cent; while there is no sort of forest management in the private forests, which are rapidly disappearing under the hand of the unchecked timber-felling contractors or the unchecked grazing accompanied by fire in the hot season at the hands of the villagers. In European countries the average forest area in a State, including State, communal and private forests, amounts to 26 per cent. In British India, a fundamentally agricultural country, the total area of forest is less than that required, and its distribution is bad.

Howard points out that the existing forest policy does not include suggestions that the forest area of the country should be increased chiefly by additional Government forest reserves. The present policy restricts itself to the ruling that agriculture should not be allowed to encroach on reserved forest to the extent of reducing the forest area below the minimum required for the well-being of the country, considered to be 20–25 per cent. Allusion is made to erosion and floods caused by the removal of forest growth in considerable parts of the outer Himalaya and other hill areas in the country, necessitating an increase of forest as an aim of post-war policy. Three ways are suggested: (*a*) by afforesting or improving impoverished areas of Government waste lands; (*b*) by bringing more private and communal lands, where available, under forest by propaganda and assistance in their management; (*c*) by the legal control of the management of private and communal forests to prevent deforestation. The Indian Forest Act contained clauses providing for control over private forests, but forest officers had found it practically impossible to enforce them. In some provinces fresh legislation is being drafted to provide for practical supervision. The suggestions of the Inspector-General are: (1) The acceptance of the aim that 20–25 per cent of British India should be brought under correct forest management, and so far as possible in each of the provinces; (2) the enactment of a Private Forest Act to supplement the present India Forest Act in each province.

Chapter 3 of the post-war proposals discusses supplies and consumers under: (*a*) general consumers, mainly urban, whose needs are mainly met by the timber trade; (*b*) local village consumers residing close to a source of forest resources; and (*c*) ordinary village consumers who live far distant from any source of forest produce. No serious problem is involved, says the writer, in respect of the first two of these classes, either the chiefly urban or the villager residing near the forest areas. It is the third class of consumers who has been inadequately provided with forest materials, in several cases, for periods which run into centuries, as, for example, in Bengal. The post-war proposals in reference to this class are of the first importance. It is estimated with more certainty than is the case with most estimates of this type that large parts of the Punjab and the North-West Frontier Province, probably 90 per cent of the plains' villages in the United Provinces, all the centre and west of Bengal, much of Bihar and the coast lands of Orissa and possibly half the Bombay Presidency contain populations with an almost completely unsupplied demand for forest produce, firewood in particular. Lack of fuel in India has involved the use of cow-dung for cooking purposes, for example, for centuries in large areas of Bengal; it is estimated that somewhere about 43,000 square miles, or 13 per cent of the whole of the cultivated tracts of India, could be manured if wood fuel were available to the peasant for cooking purposes. In other words, for large areas or sections of the countryside, if fuel can be made by the formation of plantations, fuel forests, or minor forests (the name by which they are called is immaterial) in small blocks carefully sited so as to be evenly situated over the forestless area concerned, a very considerable amount of manure will be directed to its rightful purpose, the land.

This proposal, the most vital one in the Inspector-General's post-war forest policy report, it is estimated, will mean the creation of 100,000 square miles of additional forest—a sufficiently formidable scheme when it is remembered that the forest staff will have to make themselves conversant with the soils of a particular tract on which it is wished to site a future block (of no large size, but compact) of forest for the provision of fuel and small house timber. Usually in India hitherto, in the districts, land has been classified into cultivated and uncultivated lands solely from the agricultural point of view, the latter being subdivided into cultivable waste other than fallow and land not available for cultivation. It is suggested that uncultivated lands should in future be classified as: (*a*) waste lands other than fallow on which minor forests could be grown (that is, fuel forests), and (*b*) land not available for forest cultivation. It is considered that such a classification will not require any elaborate machinery, since the selection of areas to be utilized for these fuel reserves could be left to the forest officers, who would be responsible for the actual planning of operations. I am given to understand that Bengal has already made considerable headway in this matter, the parts of the country intimately concerned in this matter having been investigated by the Chief Conservator of Forests and members of his staff and preliminary proposals drafted. If the work is to meet with success from the outset, as is most desirable, it would appear essential that an increase of forestry staff should be made, and that carefully selected members should be detailed to carry out these far from easy operations, which will be of such vital importance to the community and the country.

On the subject of the reserved forests of India as a whole, such was the degree of efficiency reached in their management that the Inspector-General is able to write that little is required to restore the departure from normal, that is, the excess war fellings; a 40–50 per cent reduction in pre-war yields for a period of five to ten years may in some cases be necessary. The true position can be determined by the revision of the working plans, which must therefore be accelerated after the War. What other country in the world with the possible, though doubtful, exception of one or two in Europe, could make such a confident statement about its war fellings and give such an estimate of the period—and so short a period—in which the excess could be brought to normal again? With such a forest record India will fully deserve all the assistance she can be given in her new effort to bring about a more even distribution of her forests, particularly those providing more especially, if not solely, for her huge agricultural population. For a higher fertility of her soils will furnish at least one answer to the question as to how she is to maintain her increasing population.

Space will not permit of following the Inspector-General's suggestions on floods, erosion and desiccation, forest research, forest education and minor forest produce. It is proposed—and the proposal has now been carried out—that the posts of Inspector-General of Forests and president of the Forest Research Institute and Colleges, which were amalgamated in 1925, with headquarters at Dehra Dun, should be separated, the Inspector-General going back to the headquarters of the Government of India at Delhi and Simla. This was a most desirable move. The idea of a federal service, which had already been suggested by Sir Jogendra Singh, was to provide for the staffing of posts under the Central Government and possibly interchangeable with men from the provinces. It would mean that the majority of the gazetted officers at the Forest Research Institute and posts such as the Andamans, Coorg, etc., and special forest officers to draw up working plans and give professional advice to individual States and agencies, would be placed on a federal list. Sir Jogendra's suggestion appears to be eminently practical and one well worth bringing to realization.

The picture would be overdrawn if it were said that this report on post-war forest policy for India and the suggestions contained in it are in many directions the most important document drawn up for India's forests since the dispatches of the Secretary of State for India and the Governor-General written in 1862, dispatches which brought about the inauguration of the Indian Forest Department.

NUTRITION IN JAMAICA

IN a report prepared by the Nutritional Committee of the Jamaica Branch of the British Medical Association, Dr. W. E. McCulloch and his colleagues have explored the future position as to nutrition and agriculture in Jamaica, when the resolutions of the Hot Springs Conference come to be implemented.

While there is little or no difficulty in formulating a dietary of what the people should eat within the list of available local and imported foods, difficulties begin when the 'how' has to be considered. It is here that one comes up against what is probably a problem common to all those countries which depend very largely on agricultural exports for their economic existence—the conflicting interests of local nutrition and the export trade. This problem is most critical in those countries which, like Jamaica, are densely populated. The suggestion made in the report under notice for the solution of this problem is the intensification of agricultural production.

Considering the report in detail, the Committee accepts the findings of the 1937 Nutritional Committee of Jamaica, and remarks that the condition has been accentuated by the War, which has limited imports. The two main findings of the 1937 Committee were that the nutritional state of a distressingly large proportion of the labouring classes must be classed as definitely bad, and that the chief features of the island's unbalanced dietary were the deficiencies of animal protein and animal fats and the excess of starchy foods.

As a standard at which to aim, the Committee adopted Plan 1 of the Hot Springs Conference (which is relatively economical and suited to a poor population) and has translated it into tons of foodstuffs necessary to feed the Jamaican population of 1¼ millions. This estimate has been compared with what Jamaica actually ate in 1942. The calculated daily calorie consumption was 1,779, as against the Hot Springs standard of 2,688. Substances eaten in excess of requirements were those of a bulky nature such as ground provisions (yams and roots of various sorts) and vegetables and fruits (other than citrous fruits); while the chief deficiencies (per man per day) occurred with milk, 1/7 oz. as compared with 20 oz.; eggs, 5 per man per annum compared with 228; fats, ¼ oz. compared with 2 1/5 oz.; grain (as flour), 2¾ oz. compared with 10 oz.; and meat and fish, 2 oz. compared with 4 oz.

The Committee then goes on to translate these deficiencies in food requirements into acres required to produce them on the basis of the present production per acre; for example, a ration of 20 oz. (1 pint) of milk per day means 60 million gallons per year, which at present production-rates means 158,750 milking cows, or including dry cows and heifers reared for replacement, 264,000 cattle. This number of cattle would require 792,000 acres to maintain them. The total acreage required (allowing for the importation of 50,000 tons of wheat and 15,500 tons of rice) under existing methods of agriculture would be as follows (in thousand acres): cereals, 83; roots, 20; pulses, 20; citrus, 3; milk, 792; beef, 1,836; a total of 2,754,000 acres. With additions for other things such as green vegetables, the total would exceed 3,000,000 acres. The actual acreage available in Jamaica, excluding some 586,000 acres in forest, towns, etc., is 2,250,000 acres, and much of this is not suitable for permanent cultivation.

Moreover, the economy of Jamaica is based on the production of agricultural produce for export to provide money for the importation of manufactured goods, flour, etc. These crops (as for example, sugar cane, 100,000 acres, and bananas, 150,000 acres) utilize the best available land for their purpose, and in total require 350,000 acres. It is thus clearly demonstrated that competition for land between export crops, food for domestic livestock and potential food for man has already reached a stage in Jamaica where it is impossible of solution if the present methods of agricultural practice continue. This is the outstanding conclusion of the Committee.

The Committee recommends therefore a complete revolution in Jamaica's agricultural system, which would include improved and more intensive methods of production. In particular, the first requirement is to increase the efficiency of the livestock industries, since there is an appalling competition for land between man and cattle. It is pointed out that Jamaica can no longer afford 2–3 acres to feed one cow giving about 300 gallons of milk, or a range steer to produce some 500 lb. of meat. A swing-over from beef to milk production is also recommended. Increased production of peanuts and soya beans would do much to supplement the meat supply. The productive land should be used in a cycle which includes cattle, but the land cannot be permitted to be used solely for beef cattle. The local production of rice on reclaimed swamps and the production of food yeast from molasses are among other items suggested; but it is pointed out that while the addition to the ration of vitamin B_1 from yeast will be an advantage, it will not reduce the need for the other constituents of a good ration for children. The Committee quotes in detail Dr. Platt's recommendations for an immediate aim for nutrition in Jamaica, but considers that these will not altogether satisfy the social needs or meet economic requirements, and so it proposes an amended dietary as a basis for agricultural policy. It is convinced that the increased production required to meet the 'intermediate diet' could then be attained by increased output of produce per acre; increased acreage should not be required. The Committee concludes by saying that it considers that by increased efficiency and harder work, the aims of nutrition and economics are attainable in the next few years, and that both can be made to fit into the requirements of the land and the farmer. Neither efficiency nor hard work can, however, be achieved unless good food is plentifully available to rich and poor alike. If higher standards of efficiency and greater output *per capita* of population as well as per unit of land cannot be achieved, then the outlook for Jamaica cannot be regarded as anything but poor.

The Committee's report is a most interesting and important document, and worthy of study by all those who are engaged in nutrition or agriculture; it can well serve as a model in method for those who are considering such problems.

OBITUARIES

Dr. Gustav Senn

Dr. Gustav Senn, professor of botany in the University of Basel, died there suddenly on the morning of July 10. His colleagues and other friends were preparing a *Festschrift* to be given him on November 9, his seventieth birthday.

Gustav Senn wrote his inaugural dissertation in 1899 on certain colonial unicellular algæ; and he dealt about the same time with several families of the lower algæ for Engler and Prantl. In several subsequent papers he discussed the arrangement of chlorophyll and 'chromatophores' in algæ and in higher plants. He wrote a useful little Flora of the Western Alps about forty years ago, and published a number of papers on the special physiology of Alpine plants in relation to light and temperature.

But Senn was chiefly remarkable for his admirable knowledge of Greek, and for his devotion to Theophrastus and other lesser sources of Greek botany; herein he was the legitimate successor to the last of our own scholar-botanists, Sir William Thiselton-Dyer. Senn had ambitious schemes in hand, including a revised text and translation of Theophrastus; but he was a slow and most cautious worker, and has left a deal of work undone. The last time I saw him, just before the War, we talked of a difficult and confused part of Theophrastus' work on "The Causes of Plants"; he had cut up and pieced together several pages of the book, and as he thought, and as it seemed to me, the re-arranged paragraphs fell simply and obviously into two separate versions of the story.

Among Senn's classical papers was one on the Theophrastean pine trees of the north-east Mediterranean: that is to say, on the stone pine, the Corsican pine and the Aleppo pine, in Macedonia, in Arcady and on Mount Ida. Another deals with "Theophrasts Differential-Diagnosen für laubwerfende Eichen"; in other words, on the various deciduous oaks, and their somewhat peculiar limitations of habitat and distribution. The number of species to be dealt with is considerable, including *Q. Robur, Aegilops, Cerris, lanuginosa, pedunculata,* and perhaps one or two more; and Senn's identification of the Greek names differs in several instances from Dyer's. In yet another paper, on the Greek fir trees, Senn argues (again against Dyer) that what Theophrastus calls the male and female fir are really distinct species. One is the common Greek fir tree, *A. Apollinis*, Link, of which *A. cephalonica* is a local form; the other, *A. alba*, Miller (= *Pinus Picea*, L.), grows further north, and forms great woods in Macedonia. A better-known and still more curious paper is one on "Oak-galls in the Historia Plantarum of Theophrastus", published in the *Transactions of the Royal Society of Edinburgh* in 1941 (see *Nature*, April 17, 1937, p. 684). Theophrastus mentions ten kinds of gall on various oaks, giving a very few words to each; and Senn succeeds in identifying every one of these, the common oak apple being the only one of which the identification remains a little dubious. Dyer identified, with more or less certainty, a vast number of Greek names of the higher plants; but he gave no heed to such things as galls, nor to the various fungi and fungoid diseases to which Theophrastus makes passing allusion. Here Senn stood alone. I asked him once if he could explain two diseases of the fig-tree which Theophrastus mentions—the so-called 'rot' (or *sphacelismus*), in which the roots turn black, and the *krados*, in which the leaves do so. He told me that the one was what the French call *la pourridie* (*Dematophora necatrix*, R. Hartig); and the other was caused by *Fumago vagans*, Pers., the sign of which is a sooty dust upon the leaves. Let the revisers of "Liddell and Scott" take note of these!

D'Arcy W. Thompson.

Prebendary Lonsdale Ragg

The death of the Venerable Lonsdale Ragg at the ripe age of seventy-nine years has deprived forestry and botanists in general of one who for many years had fostered by all means in his power an interest in trees. He was born in 1866, the son of a country clergyman in Shropshire, and no doubt his upbringing in that delightful county did much to influence his work in future years. His clerical career was distinguished, for he was Prebendary of Buckden in Lincoln Cathedral and had been Archdeacon of Gibraltar since 1934. He was, in fact, particularly interested in the Mediterranean countries, and in his earlier years had served in various chaplaincies in Italy and elsewhere, publishing many theological theses on the history of religion in that region.

To a wider public, however, Lonsdale Ragg was known for his interest in trees, and particularly for his beautiful illustrations of tree-life. He had been editor of the quarterly magazine *Tree Lover* from 1932, and its pages are full of his contributions and of his delightful sketches of trees. These black-and-white illustrations of typical trees were not only most artistic, but were also very accurate as to detail. Although he usually concentrated on depicting particular specimens, some of his work shows that he was also equally competent in producing more general scenes, as is exemplified by his scenes of "Bath after the Blitz" and "The Charm of Foliage"—a drawing of Sydney Gardens in Bath. It was in this city that he had made his home in recent years, and its picturesque surroundings gave him ample scope for practising his art. Many of his sketches consist of details of the trunk and lower branches of some particular giant, and he was particularly interested in famous and historic trees, especially large and well-grown specimens. There is a sketch of a specimen of *Robinia pseudoacacia* at Warminster, with a height of 85 ft. and a girth of 21 ft. 6 in., which is typical of his work.

Lonsdale Ragg kept up his interest in trees until the end of his life. He was a frequent visitor to Kew until recently, when increasing infirmity rendered the journey from Bath under war-time conditions difficult. He was indeed a tree lover, and one of his last communications with the Royal Botanic Gardens concerned the dimensions of a specimen of Monterey cypress which he had discovered near Lyme Regis. He had hoped that this was the largest specimen in the British Isles and was somewhat disappointed when it was pointed out that larger specimens existed.

As a man Lonsdale Ragg possessed great charm, and his enthusiasm together with his old-world courtesy endeared him to all with whom he came in contact. His writings, his sketches and above all his delightful personality will be missed by all tree lovers.

G. Evans.

Sir William H. Ellis, G.B.E.

Sir William Henry Ellis, who died at Sheffield on July 4 at the age of eighty-four, was the fourth son of John Devonshire Ellis, one of the original partners in John Brown and Company, armour plate and steel manufacturers of Atlas Works, Sheffield.

Sir William was born at Thurnscoe Hall in the county of York on August 20, 1860. He was educated at Uppingham School, and entered the works of Tannett Walker and Co., Ltd., of Leeds, in November 1878, passing through their various shops and drawing office. In 1882 he had charge, on their behalf, of the erection of a vertical blowing engine at some copper smelting works in Servia, and afterwards was, for two years, a foreman in their erecting shop in Leeds. In October 1885 he went to Sheffield to take charge of the erection of a 4,000-ton hydraulic forging press, a pair of hydraulic pumping engines and two 150-ton overhead travelling cranes in connexion with the press. At the completion of this work in October 1887, he entered the employment of John Brown and Co., Ltd., Sheffield, as under-manager of their forge department. He was appointed a director of the Company in 1906 and became managing director in 1919.

Throughout his career Sir William displayed marked ability in technical, commercial and administrative work, and in addition, found time to render valuable public service. Among the many positions he has occupied, it is worth while putting on record here that he had been president of the Institution of Civil Engineers, of the Iron and Steel Institute, of the Sheffield Society of Engineers and Metallurgists, and of Section G (Engineering) of the British Association at the Glasgow meeting in 1928. He was Master Cutler in 1914, 1915, 1916 and 1917. He was a member of the Council of the University of Sheffield, of the Executive Board of the National Physical Laboratory, of the governing body of the Imperial College of Science and Technology and of the Cambridge University Appointments Board. He was also a member of the Committee of Privy Council for the Department of Scientific and Industrial Research, and of the Government committee on drainage in the Doncaster area.

Sir William was a member of the Swiss Alpine Club, a keen and intrepid mountaineer, and did much to assist Swiss guides in their retirement. He climbed the Matterhorn on his seventieth birthday. The Derbyshire moorlands were an open book to him. He looked forward to his week-ends, when walks of 16–20 miles over the wild heather-clad moors and fells of the Pennines were his delight and afforded him mental rest, in invigorating air, and equipped him for the work of the ensuing week.

On the artistic side Sir William was an accomplished organist, and loved to entertain friends in the evenings with selections from famous composers.

Sir William was a man of outstanding ability, tenacious in the pursuit of his object, and prior to his retirement from John Brown and Co., Ltd., was extremely active in the industrial life of Sheffield. He was a warm-hearted friend, and his passing leaves a gap in the ranks of Sheffield's old prominent citizens.

J. F. Bridge.

We regret to announce the following deaths:

Prof. J. Davidson, head of the Department of Entomology, Waite Agricultural Research Institute, and professor of entomology in the University of Adelaide, aged sixty.

Mr. J. S. Highfield, consulting engineer, a past-president and honorary member of the Institution of Electrical Engineers, on August 15, aged seventy-three.

Prof. L. Wertenstein, formerly of the Mirosław Kernbaum Radiological Laboratory of the Warsaw Society of Sciences, during a bombardment of Budapest in January 1945.

Prof. J. T. Wilson, F.R.S., emeritus professor of anatomy in the University of Cambridge, on September 2, aged eighty-four.

NEWS and VIEWS

Dr. H. J. Gough, C.B., M.B.E., F.R.S.

The announcement that Dr. H. J. Gough has relinquished the post of director-general of scientific research and development, Ministry of Supply, to become engineering chief of Messrs. Lever and Unilever Ltd., is of particular interest at the present time, since it means that British industry will have the full benefit of the accumulated experience of an engineer-scientist who has shown outstanding ability, first as an individual scientific investigator and then, during the war years, as one of the most responsible scientific administrators in the Government service. As a young man, Dr. Gough served with distinction in the Royal Engineers in the War of 1914–18 and then returned to the Engineering Department of the National Physical Laboratory to carry out the valuable researches on the causes of deformation and failure of engineering materials with which his name will always be associated. He rapidly became recognized as the leading authority in Great Britain on the important subject of the behaviour of metals under repeated or fatigue loading, and although always interested in the application of his researches to engineering practice, demonstrated very fully in his own work how invaluable it is to utilize fundamental metallurgical and physical science in the solution of engineering problems. Dr. Gough succeeded the late Sir Thomas Stanton as superintendent of the Engineering Department of the National Physical Laboratory in 1930, and in this position not only continued his personal researches, but was also responsible for the initiation of many valuable researches in engineering materials and design, applied fluid mechanics, ballistics and lubrication. His researches and authoritative lectures did much to enhance the high reputation of the National Physical Laboratory in engineering research. In 1938 Dr. Gough was appointed the first director of scientific research at the War Office, and almost immediately had to face the tremendous task of organizing and directing the scientific activities of the newly created Ministry of Supply. This work called for all his abilities and almost inexhaustible energy, and can perhaps be summed up by saying that Dr. Gough, perhaps more than any other individual, was responsible for the many advantages which applied science has been able to give to the British Army in its successful fight.

Chair of Geography at the London School of Economics

Prof. Ll. Rodwell Jones

THE retirement of Prof. Llewellyn Rodwell Jones under the age-limit marks the termination of twenty years tenure of the chair of geography in the University of London at the London School of Economics, where he succeeded Sir Halford Mackinder as head of the Department. After a period as a school-master, he lectured for a year in the University of Leeds, before serving during 1914–19 in the West Yorkshire Regiment, which he left with the rank of major and with an M.C. to take up a lectureship at the London School of Economics. Under Mackinder's guidance, Rodwell Jones and his sister (afterwards Dr. Hilda Ormsby) laid the foundations of one of the strongest schools of geography in Britain, very wisely joining forces with King's College, London. Under this inter-collegiate arrangement, Rodwell Jones secured for his specialist staff the ideal opportunities of combining research and lecturing in their own fields, and avoided what is so often the curse of university departments, namely, too great a burden of lecturing on any one member of the staff. As a result, a constant stream of original work has emanated from the Department.

Rodwell Jones's own interests were particularly in the historical and economic geography of North America, and it was after a period as visiting professor in the University of Chicago that he published in conjunction with a former student of the School, Dr. P. W. Bryan, his standard work on North America, now in its seventh edition. Always constructively critical, his meticulous attention to detail is well shown in his volume on "The Geography of London River" (1931). His influence on the progress of geography in Great Britain cannot be measured by his published works. As an ideal chief, an ever-helpful colleague, and inspiring lecturer, he succeeded in imparting an enthusiasm for his subject to successive generations of students. It is no accident that those students now occupy the headships of geography departments in half a dozen universities in Britain and the Empire.

Dr. L. Dudley Stamp

THE appointment of Dr. L. Dudley Stamp to the chair of geography at the London School of Economics and Political Science, made vacant by the retirement of Prof. Rodwell Jones, does not involve him in any change of location, for he has long held a Cassel readership at the School. No doubt he will re-establish the fruitful connexion with the Geography Department at King's College, which was broken by the War. Prof. Stamp has travelled in most parts of the world, and has spoken and written on many subjects, but his best-known work is that of the Land Utilisation Survey. This series of maps and memoirs on the counties of Britain has been found invaluable, not only in academic regional studies, but also as a guide to planning and reconstruction, particularly in respect of rural land use. As regards the latter, Prof. Stamp is chief adviser to the Ministry of Agriculture. Like his late brother, Lord Stamp, he is a persuasive and lucid speaker and writer, and has done much 'to carry geography into the market-place'; not, of course, without danger to his reputation, since it is almost impossible to be simultaneously simple and precise. But Ministers are impatient of indeterminacy, and of exact answers promised for delivery fifty years hence. They are required to take action here and now, and the scientific worker must take the risk of offering advice based upon a first approximation. It was not very long ago that Prof. Stamp's gift of exposition carried all the lay members of an important committee with him, leaving the only other expert, an economist (who in this instance was probably in the right), to carry his orthodoxy into the dusk of a minority report, and thence to Cambridge. But more than one economist now recognizes that the location of industry (to take but one example) has some relation to locality, and since geography is the minute study of locality and its significance, the association of a Department of Geography with a School of Economics holds possibilities of real usefulness. These possibilities, it is to be hoped, Prof. Stamp will have the opportunity to develop.

Science and Education in India

MR. L. J. F. BRIMBLE, joint editor of *Nature*, has recently returned from a short but intensive tour of India and Burma, where he not only made cultural and educational contacts with British and other troops in South-east Asia Command, but was also able to visit a number of scientific and educational institutions in various parts, mainly Calcutta. It is hoped, in due course, to publish a more extensive account of the contacts made, but men of science in Britain will be glad to know that the Editor has returned inspired by the enthusiastic way in which their Indian colleagues are working for the advancement of science and education in India. The hospitality extended to him by Indian men of science left nothing to be desired; in fact, he found it quite impossible to accept all invitations. Though it is not possible, at present, to discuss details or mention all individuals, it is impossible, even in a short note, to omit mentioning the kindness of Prof. M. Saha, professor of pure physics in the University of Calcutta. Under Prof. Saha's guidance the Editor was able to see most of the departments of the physical sciences in various colleges of the University. He saw the cyclotron which, after three years work on it, is nearing completion. It only remains for a few parts to arrive from the United States before research work with this instrument can begin. Prof. P. N. Ghosh, Prof. S. K. Mitra and Prof. S. N. Basu were also helpful in showing the work going on in the departments of pure and applied physics. The pure and applied chemistry departments were visited under the guidance of Prof. J. N. Mukherji and other professors. Here the Editor had the honour of visiting the room in which Sir P. C. Ray lived and died.

Many biology departments were also visited, mainly at the University College of Science (under the guidance of Profs. S. P. Agharkar, H. K. Mookerjee and their assistants) and at Presidency College (under the guidance of Profs. J. C. Sen Gupta, S. Banerjee and others). The work of other science departments was explained by their various heads and assistants. Mr. Brimble is particularly grateful for the kind hospitality of the statistician, Prof. P. C. Mahalanobis, professor of physics in Presidency College and the founder of the Statistical Laboratory, Calcutta. Mr. Brimble was able to address the students of the University and also certain sections of the staff. He had a fruitful discussion with Dr. R. Pal (vice-chancellor), Dr. B. C. Roy (president of the Post-graduate Department), Dr. S. Mookerjee (former vice-chancellor), the Hon. Justice Mr. C. C.

Biswas, and other members of the University Senate. Under the guidance of Dr. K. Biswas, an interesting visit was paid to the Royal Botanic Garden, Sibpur, of which Dr. Biswas is superintendent. There he was able to meet other botanists, including Prof. S. A. Bose, of the Carmichael Medical College, Prof. J. C. Sen Gupta, of Presidency College, Dr. P. C. Biswas, anthropologist in the University, and others. Some time was also spent in visiting the All India Institute of Hygiene and Public Health, the School of Tropical Medicine and other centres of medical research. Many other men of science were met, both in Calcutta and Allahabad and elsewhere. Of more special interest was the visit paid to the offices of *Science and Culture*, of which Prof. Saha is an Editor. These offices are situated in the University College of Science.

The Editor has been asked to convey greetings to British men of science from their Indian colleagues, and has also brought many private messages for individuals. He hopes to convey these in due course.

Peoples of India

The condensation of a description of a vast and complex country like India into a booklet of some 85 pages, including illustrations, is no mean feat, especially when the result is so clear and informative. Wm. H. Gilbert, jun., has done this in War Background Studies, No. 18, entitled "Peoples of India", issued by the Smithsonian Institution. Starting with the environment (geographical, climatic and biological), the author passes on to the inhabitants; these are of diverse origins as is well known, and thus lay the foundations for the complicated aggregation that is India. Most of the so-called races of man are represented there. When it is realized, moreover, that there are about 180 different languages, apart from 550 dialects, in the country, there is no denying that the difficulties of administration are great. Although India shows great ethnic diversity, there is at the same time a certain cultural unity. The people as a whole may be described as sharing certain traits such as conservatism, a lack of time sense, a love of social prestige, a highly developed religious sense and a strong devotion to the family. The mental abilities of certain castes are unquestioned, as shown by their metaphysics and by their art, to mention only two examples. Caste coupled with religion is perhaps the outstanding characteristic of India. The caste system, faulty though it may be, at least has the merit of bringing order into what might otherwise be a discordant assemblage of peoples. The book ends with a short account of Indian contribution to the War, and it is illustrated with fine photographs which do much to emphasize the essential contrasts in India of great riches and abject poverty, of fine buildings and squalid huts.

Food Policy in Britain

Discussion Circle, No. 2 (Craig and Wilson, 70 Bath Street, Glasgow), opens with an article by Sir John Boyd Orr, entitled "If I were Minister of Food in Peace-time". The first thing that might be done, says Sir John, is to get out a statement of the findings and recommendations of the United Nations Food and Agricultural Conference, the delegates of which represented 80 per cent of the world's population. They unanimously declared that: (1) the kind of food needed is known; (2) even in the best fed countries, 20–30 per cent of the population do not obtain sufficient of the right kinds of food essenti for health; (3) lack of sufficient of the right kin of food is the cause of disease, physical disabilit and untimely death; (4) the first cause of lack food is poverty; (5) we have the knowledge an ability to produce all the food needed. The Conferen also recommended that every nation should provi a diet adequate for the health of the citizens, an these recommendations have been accepted so far they affect Great Britain. If, continues Sir Joh you were Minister of Food, the first decision whi you would have to make would be whether yo would carry out these recommendations, and, befo you made this decision, you would have to consid what would happen if you did carry them ou Opinions on this will differ. Sir John bases his esti ate of what would happen on what did happen whe we changed the national diet between the War 1914–18 and the present time. During this peri the average consumption of foods of special val for health increased by about 50 per cent, and the was also a remarkable improvement in nation health. Certain deficiency diseases, such as ricket almost completely disappeared; children were nearl three inches taller, and infant mortality fell by mo than 30 per cent, and deaths from tuberculosis b more than 50 per cent. Other factors undoubtedl helped to produce this result; but the improvemen in the national diet was, Sir John thinks, the ou standing change. During the recent War, the foo policy of Britain has been based upon nutrition needs. The special needs of mothers and childre have been provided for, and the diet of the workin class is therefore now better than it was before th War.

To maintain this improvement Sir John sugges that the Government should appoint a food an agricultural commission. The commission would nee to own, or at least to control, the processing centr such as flour mills, slaughter houses, bacon factori and milk depots if it were to give a guarantee market. The wholesale food trade would purcha from the commission all its supplies at a wholesa price calculated in such a way that, by the cheape method of distribution, namely, cash and carr retail prices would be adjusted to the capacity of th poorest families. The provision for the poor of a adequate diet would go far to abolish poverty itsel and the guarantee that there would be no lack food adequate for health would do much to abolis one of the worst fears of poverty.

New Zealand Forest Service

The annual report of the New Zealand State Fores Service for 1944 (Gov. Printer, Wellington, 1944) i fully up to pre-war standard both in make-up an contents. A separate report on post-war forest polic being under preparation, only a brief reference to thi subject is made. In one of the reports pub lished during the War, the Department pointed ou that the only realistic and economic solution of th problem of erosion control lies in Dominion-wid control of land-burning operations. This contentio is now winning wide recognition, and suppor from the various advisory committees functionin under the Soil-Conservation Council is being re ceived. It is added that a great step forward wil be achieved if the newly appointed catchment board concentrate upon this phase of their operations During the War, the Department has been immersed as is the case with most other forest departments, i war production. The shortage of man-power was still a major problem. Some alleviation resulted from the return of forestry units from Great Britain and of men from the Middle East, together with a number returned from the Armed Forces within New Zealand. The chief problem was to maintain the large number of saw-mills at maximum production; the continued transfer of semi-skilled and inexperienced workers from other industries to forest and saw-milling work making it difficult to maintain a high production. The cessation of construction of defensive works against a Japanese invasion and the recent release of a substantial number of men from the Pacific theatre of war for service in the timber industry has resulted in a material improvement.

Ball Lightning

The *Ayrshire Post* of August 10 contains a description of what is described as a fireball, which caused considerable damage on the night of Sunday, August 5. The so-called fireball was associated with a thunderstorm which reached Ayr from the north shortly before 8.30 and passed quickly away. It caused serious damage to a house at 6 Teviot Street, Ayr. From the descriptions of those who saw the phenomenon, it is clear that, as it accompanied a flash of lightning, it was not the fireball familiar to the astronomer but a case of ball lightning. Mr. John Don, of 1 Gardenrose Path, Maybole, Ayrshire, who directed our attention to the above article and who also saw the ball, says that it fell very quickly. Ball lightning, it may be recalled, was photographed before the War on at least one occasion, and was included by Sir George Simpson, former director of the Meteorological Office, in his studies of atmospheric electricity.

White Dwarf Binaries

The April issue of *Sky and Telescope* contains a short notice of white dwarfs which form binary systems, the first discovery being made recently by Dr. W. J. Luyten. The twins were found in Antlia and are of magnitude 14, nearly identical in colour, and apparently genuine members of the dwarf species. Originally a wide double star had been announced, but on examining the star with the 36-in. Steward Observatory reflector, Dr. Luyten found that the fainter component of the wide pair was merely an optical companion, but the brighter component appeared elongated. Verification of the double character of the star was obtained from Mount Wilson, where Dr. Walter Baade secured a photograph with the 100-in. telescope which revealed two stars separated by $3''$ and differing by 0·3 magnitude. A tentative estimation of their orbit shows a period of the order of 250 years, and it is hoped that in ten years the period will be determinable with a fair precision. It is conjectured that the twins are each intrinsically 1,600 times less luminous than the sun and have diameters smaller than that of the earth. Assuming that their masses are typical—about that of the sun—their densities are about 25 tons per cubic inch, or more than $1\frac{1}{2}$ million times the density of water.

Department of Forestry, University of Oxford

The following appointments have been made in the Department of Forestry of the University of Oxford: Dr. W. R. Handley has been appointed microbiologist. He graduated in botany at the University of Leeds in 1935 and was awarded the Ph.D. for his studies on the structure, development and physiology of the xylem of trees. He then turned to bacteriology as research assistant to Dr. F. C. Happold, and in 1939 was appointed lecturer in that subject at the University of Birmingham. During the War he has been working at a public health laboratory at Wellington (Salop) and Hereford. Dr. L. Leyton, who has been appointed tree physiologist, also graduated in botany at Leeds (in 1938) and continued his studies as a University research scholar, working on the physiology of the monocotyledonous leaf, obtaining his Ph.D. in 1941; he has been at the Telecommunication Research Establishment during the War. Squad.-Leader G. W. Dimbleby has been appointed ecologist; he graduated in botany at Oxford in 1939, and has worked on oxidation-reduction potentials as measures of soil activity. It is intended that the work associated with these appointments shall be focused on the relations between tree-growth and soil factors.

Announcements

After evacuation for a period of three years to Saratov, the Leningrad Society of Naturalists has resumed its activities at the State University of Leningrad. Several meetings, general and sectional (zoology, botany, physiology and geology), were held during last spring, and publication of the *Travaux* is also being started.

A new series of lectures on "How it Works in Photography" has been arranged by the Scientific and Technical Group of the Royal Photographic Society of Great Britain to be held at 16 Prince's Gate, London, S.W.7. The first of the series, entitled "Camera and Optics", will be delivered by Dr. G. B. Harrison on September 25 at 6 p.m.

Catalogue 10 recently issued by Schuman's, 20 East 70th Street, New York, contains more than 350 items of old medical and scientific works of the sixteenth and seventeenth centuries. Special mention should be made of works by Boyle, Harvey and Willis, of whom contemporary portraits are inserted. Among many other books deserving attention are: John Banister's "Historie of Man" (1578); Wordsworth's copy of Sir Thomas Browne's "Urn Zurial" and other works; William Clowes' "On the Working Gallilus" (1683); Culpeper's "Physical Directory" (1651); Sir Thomas Elyot's "Castel of Helth" (1541); William Gilbert's "De Magnete" (1600); Peter Levens's "Right Profitable Book for all Diseases. Called the Pathway to Health" (1582); Peter Lowe's "Discourse of the Whole Art of Chyrurgerie" (1634); and Morton's "Phthisiologia or A Treatise of Consumptions" (1694). Frontispieces of many of the works are inserted.

Errata. In the article by Dr. Julian Huxley on "Evolutionary Biology and Related Subjects" in the series dealing with Science in the U.S.S.R. (*Nature*, September 1), on p. 255, col. 1, line 41, for "Khostova" read "Khvostova", and on p. 256, col. 1, lines 26–29, it is stated that "The most interesting are in black-cock, where more than 200 million specimens from the markets for some four hundred years had been gone through". For "four hundred years" read "forty years".

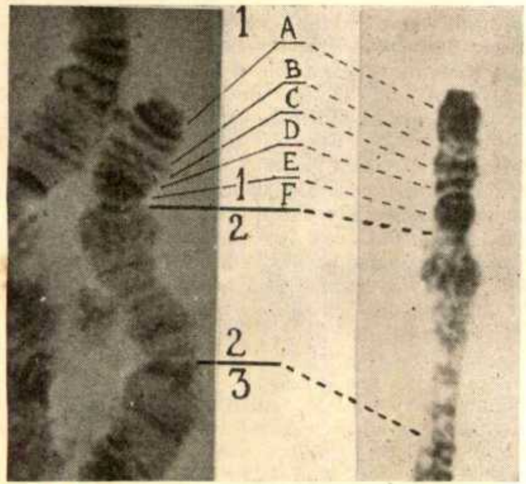
Phosphatase on Chromosomes

WHEN the tissues of Craniata are treated by the technique of Takamatsu[1] and of Gomorri[2], alkaline phosphatase is found to be present in the cell nuclei. Willmer[3] has observed that in mitosis in tissue cultures the nuclear phosphatase is concentrated on the chromosomes. One of us (J. F. D.), in collaboration with Dr. H. B. Fell, has found phosphatase on the chromosomes in tissue culture mitoses, and in the mitoses of healing wounds. That the enzyme is indeed in the cell nuclei may be shown in many ways[4]; for example, on heating dry rat kidney sections phosphatase not in the nuclei is destroyed more rapidly than is nuclear phosphatase, so that, by careful timing, sections may be obtained in which only the nuclei contain active phosphatase.

In view of these observations, we thought it desirable to study the distribution of phosphatase on the giant salivary chromosomes of *Drosophila*. Larval salivary glands were fixed in 1 or 5 per cent acetic acid for a few (1–4) minutes, squashed, and the squashes immersed at once in 95 per cent alcohol. The cover slips were lifted immediately to check destruction of phosphatase, which may be caused by prolonged contact with acetic acid. These squashes were then treated by the technique of Takamatsu and Gomorri: this showed the phosphatase to be distributed apparently in bands.

While the phosphatase appears to be situated at the Feulgen positive bands, the amount of phosphatase at any place as judged by the intensity of blackening is not absolutely related to the amount of nucleic acid at the same place, as judged by the intensity of staining shown by acetocarmine preparations. Thus in the case of the left (distal) end of the long arm of the *X*-chromosome, the photomicrographs reproduced herewith will demonstrate the similarities and differences. Taking the acetocarmine staining of the bands as a standard, it appears that 1 *C* and *D* are relatively stronger, while 1 *B* 1–3 are somewhat weaker. The normally dark bands of 1 *E* and *F* are also somewhat weaker and appear to be surrounded by a diffuse cloud of blackening. These differences in relative staining make the identification of the parts of individual chromosomes by means of the standard maps a somewhat precarious proceeding. Nevertheless, the phosphatase bands do give a general pattern strikingly similar on the whole to the more familiar carmine-stained preparation.



(*a*) (*b*)

PHOTOMICROGRAPHS OF LEFT END OF *X*-CHROMOSOME IN SALIVARY GLANDS OF FEMALE *Drosophila melanogaster* LARVÆ: (*a*) STAINED IN ACETOCARMINE, (*b*) STAINED BY TECHNIQUE OF TAKAMATSU AND OF GOMORRI TO SHOW ALKALINE PHOSPHATASE. THE PARTS OF THE CHROMOSOMES ARE NUMBERED AND LETTERED IN ACCORDANCE WITH BRIDGES' (1938) STANDARD *X*-CHROMOSOME MAP.

This apparent coincidence between sites of enzyme activity and of genetic activity suggests that we have here an indication of a process whereby genes influence cellular activity, and is, we believe, the first experimental indication of the nature of such processes.

Pigments and Chromatophore Reactions of *Polycelis nigra* and *Planaria lugubris*

IN 1938, I observed that the chromatophores of *Planaria lugubris* and *Polycelis nigra* expand in light and contract in darkness. My experiments have recently been repeated with similar results; and in addition the effects of adrenaline and ergotine have been noted. In every case the chromatophores showed normal primary responses (as do the chromatophores of less primitive animals, for example, leeches[1] and sea urchins[2]). They had no influence upon the general coloration of the animals.

Variations in colour appear among Triclads of the same species living side by side. For example, two black, five dark brown, four light brown or grey, five pinkish and one almost white specimens of *Polycelis nigra* have been found underneath a single stone. These variations are due to different depositions of melanin in the skin.

Two typical habitats were selected: one under stones in a slow-running stream (Vicar's Brook) from chalk springs to fen; the other in the axils of leaves of *Glyceria aquatica* in a creek of the Cam (by Fen Causeway). Counts were made in each habitat, care being taken to remove every animal from each stone or plant investigated.

	Under stones		In the axils of leaves			
	P. nigra		*P. lugubris*		*P. nigra*	
	No.	per cent	No.	per cent	No.	per cent
Black	61	15·5	—	—	1	0·7
Dark brown and dark grey	175	44·5	45	67·0	18	12·0
Light brown and light grey	123	31·0	22	33·0	115	78·5
Pink	32	8·0	—	—	11	7·5
White	4	1·0	—	—	2	1·3

From these results it can be seen that the average colour of *Polycelis nigra* and *Planaria lugubris* living in the axils of the leaves of *Glyceria aquatica* (a relatively light habitat) is lighter than that of animals living under stones (a dark habitat) where there is a much greater colour-range. *Planaria lugubris* tends to be darker than *Polycelis nigra* living in the same habitat. The temperature of the water was taken on a number of occasions and varied between 7° C. and 17·5° C. but was consistently the same in the two habitats.

By means of controlled habitat experiments I have shown that colour depends neither upon light nor temperature. No breeding experiments have yet been made to determine whether coloration is hereditary.

I am indebted to Dr. J. E. Smith and Dr. F. G. W. Knowles for much helpful advice.

Production of Extracellular Starch in Cultures of Capsulated Yeasts

IN the course of a study of the growth requirements of different yeasts, it was unexpectedly found that cultures of *Torulopsis rotundata* gave a steel-blue colour reaction with iodine. The cells of this yeast were grown in a simple inorganic salt medium with glucose as source of carbon, ammonium sulphate as the source of nitrogen and a supplement of thiamine as a growth factor.

The substance responsible for the colour reaction was found to be present in the medium as well as in the large capsules by which cells of this species are usually surrounded, but could not be detected within the cells. It was precipitated from the cell-freed medium by alcohol in the form of white thread-like masses. Several grams were prepared in this way, and after purification the following properties could be demonstrated: the substance dissolves slightly in cold water giving a colloidal and opalescent solution. Molisch test was positive, protein test negative. Treatment with hot 60 per cent potassium hydroxide did not impair the iodine colour reaction. A spectrophotometric analysis of the iodine complex revealed an extinction curve identical with an iodine preparation of pure potato amylose. Acid hydrolysis produced reducing sugar. The solution was practically free from nitrogen. Reactions for ketoses, uronic acids and methyl pentoses were all negative. The fermentation test of the hydrolysed material with bakers' yeast showed that only about 50 per cent of the reducing sugar, calculated as glucose, is fermentable. The unfermented residue gave a strong reaction for pentose. Amylases of plant and animal origin caused complete disappearance of the iodine colour reaction with simultaneous liberation of reducing sugar which, calculated as maltose, corresponded to about 30 per cent of the total weight. The fraction precipitated with alcohol after the action of amylase gave strongly positive reactions for pentose.

These results seem to justify the assumption that the material contains at least two different polysaccharides one of which corresponds to the amylose fraction of the starch of green plants, the other being a pentosan.

A great variety of carbon compounds other than glucose including aldo- and keto-hexoses, disaccharides, pentoses, methyl-pentose (rhamnose), polyalcohols and organic acids permitted growth of the yeast in the synthetic medium with simultaneous production of the amylose fraction. Cori ester and polysaccharides (inulin, starch, glycogen) were unsuitable sources of carbon for growth and failed to maintain amylose production even when a heavy inoculum of cells was used. On the other hand, not all sources of nitrogen used by the yeast enabled the formation of amylose. If, for example, the yeast is grown in a medium with either peptone, urea or potassium nitrate instead of ammonium sulphate, an extracellular polysaccharide is produced which gives a positive test for pentose but is entirely free from amylose. It can be demonstrated, however, that the production of the amylose does not depend in principle on the nature of the nitrogen compound but on the *p*H which is established during the utilization of nitrogen by the micro-organism. Amylose formation was observed only if the reaction was below *p*H 5. If the yeast is grown with ammonium sulphate or chloride as sole source of nitrogen, a steady lowering of the *p*H occurs as the sulphate or chloride ion is set free, whereas with potassium nitrate, urea and peptone an alkalinization results. Correspondingly, when calcium carbonate is added to the ammonium sulphate medium, the formation of amylose is suppressed; whereas the buffering of the reaction at a *p*H below 5 leads to a production of amylose even in a medium containing peptone as sole nitrogen source. In conclusion, it may be said that production of amylose by *T. rotundata* only takes place if the medium is favourable to good growth and maintains during growth a reaction below *p*H 5.

Twenty-five different yeast strains belonging to various taxonomic groups, *Saccharomyces*, *Schizosaccharomyces*, *Hansenia*, *Willia*, *Monilia*, *Rhodotorula*, *Torulopsis* (uncapsulated), produced no amylose when tested in the conditions defined above. Among the capsulated *Torulopsis* yeasts, the only species other than *T. rotundata* available to us was the pathogenic *T. neoformans*, also known in the medical literature under the synonyms of *T. histolytica* or *Cryptococcus hominis*. This strain produced amylose in exactly the same conditions as *T. rotundata*.

The serological properties of the extracellular polysaccharides described above are at present under investigation.

Antibiotics from Moulds

THE antibiotic for which the structure anhydro-3-hydroxymethylene-tetrahydro-γ-pyrone-2-carboxylic acid has been proposed[1] was detected in the metabolism solution of *Aspergillus clavatus*[2] (clavacin)[3], was isolated in crystalline form from *Penicillium claviforme* (claviformin)[4], *P. patulum* (patulin)[1] and *A. clavatus* (clavatin)[5]. The chemical nature of the product was investigated[1,5] and the structure given above was proposed[1]. The product has also been isolated from the metabolism solution of *P. expansum*[6], *A. giganteus*[7], *P. melinii*[8] and *Gymnoascus* sp.[9].

We have now shown that the same substance is responsible for at least part of the antibiotic activity reported[9,10,11] as being produced by the following moulds: *Penicillium urticæ* Bain. (N.C.T.C. No. 1215); *Aspergillus terreus* Thom (N.C.T.C. No. 981); *Penicillium expansum* (Link) Thom (N.C.T.C. No. 5612). (The production of this inhibitor by a number of unspecified strains of *P. expansum* was reported[6] two years ago.)

In each case the substance was isolated from the crude culture fluid by adsorption on charcoal, elution with 80 per cent acetone, and extraction of the concentrated acetone-free eluate with ether in a liquid-liquid extractor for several hours. Crude crystalline inhibitor separated from the concentrated ether after 1–2 days in the refrigerator and was recrystallized from hot chloroform. Identity with the authentic substance was established by mixed melting point, analytical figures, *p*H stability, antibacterial properties and chemical tests.

All three moulds were grown on liquid media in layers 1–2 cm. deep, at 24° C. for 6–10 days; antibiotic action was shown on a number of media by each mould, but the particular media from which the inhibitor was actually isolated were: *P. urticæ*, Czapek-Dox; *A. terreus*, Czapek-Dox, also 2 per cent malt extract; *P. expansum*, potato-dextrose. In the case of *A. terreus* some other inhibitor is produced under certain conditions. This is being studied.

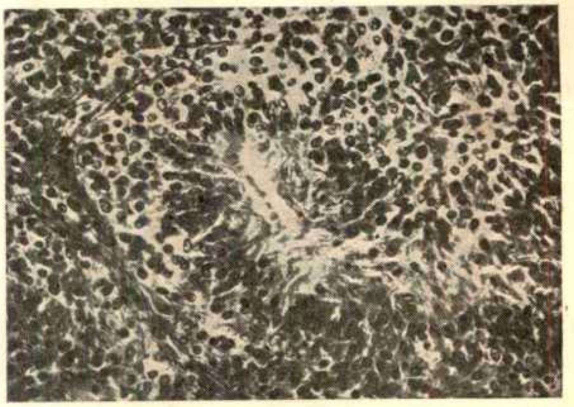
Glioma in a Rat Fed with 2-Acetyl-amino-fluorene

MALIGNANT tumours of nerve tissue have been produced experimentally in mice of pure strains by several authors. In rats, repeated unsuccessful attempts have been reported; but Russell[1] has recently given convincing evidence of positive results. All successful results have been achieved by direct action of the carcinogenic hydrocarbons (mainly methylcholanthrene) upon the nerve tissue, by way of crystals or pellets implanted in the brain substance. The result reported below refers to glioma-induction in a rat by the oral administration of a new carcinogenic agent, 2-acetyl-amino-fluorene.

The carcinogenic activity of 2-acetyl-amino-fluorene was discovered by Wilson *et al.*[2] and has been investigated in Great Britain by Bielchowsky[3], to whom we are indebted for a generous supply of the substance. The interesting feature of its action is the variety and multiplicity of the neoplasms provoked by oral administration.

The rat which developed a glioma was one of twelve which were fed from the age of two months for twenty-four weeks on a standard diet in which was incorporated 0·5 gm. of the substance in 1 kilo of food. Of the twelve rats, seven are still alive and well. Four have developed tumours; study of the fifth is not yet complete. Of the four which had tumours, one had a malignant hepatoma; another a mammary cancer and an auricular epithelioma; a third, a mammary cancer, two epitheliomas of the ductus acusticus and a hepatoma; the fourth, the subject of this note, a glioma.

The rat with the glioma first gave signs of a brain tumour by inco-ordination of movement and by a slight paresis. Two weeks after these signs were noticed, the animal died. At the post-mortem examination the only abnormality present was the asymmetry of the cerebral hemispheres, with the left obviously and regularly enlarged in its frontal part. The enlargement was accompanied by a loss of the normal aspect and vascularity of the cerebral surface. Sectioned after fixation, the left hemisphere showed the existence of a voluminous infiltrating tumour mass extending throughout the olfactory bulbs, which were later found to be totally invaded by the new growth, and the white matter of the frontal and temporal lobes, gradually diminishing backwards and leaving the cortex almost intact. The anterior and main parts of the lateral ventricle were filled with tumour tissue but the posterior horn was patent. At the level of the olfactory bulb and part of the frontal lobe the tumour invaded the leptomeninges, spreading along the subarachnoidal spaces to the cortex of the left and right sides by way of the perivascular spaces.



Microscopically, the tumour shows an almost uniform mass of small cells, mostly with round nuclei and short elongated cytoplasm. In some parts the cells are arranged in 'rosette' or palisade fashion with converging processes as shown in the accompanying illustration. Some mitoses are present. There are few blood vessels but no necrotic zones. These characteristics lead to the diagnosis of the tumour as a glioma belonging to the type 'glioblastoma isomorphe' according to the Rio-Hortega[4] classification. Further structural details will be published later.

The extraordinary rarity of spontaneous gliomas in the rat and the time of the appearance of the tumour, simultaneously with the other tumours in the series, justifies the opinion that this is a chemically induced neoplasm. The small number of animals used does not permit of any conclusion about the relative incidence of this type of tumour among the many produced by the same agent. With regard to previous experiments on glioma formation, it seems evident that when the carcinogenic substance is administered, as in our case, by a systemic route, the pathogenesis of the tumour must be nearer the natural glioma development than if a massive amount of the agent is artificially brought into direct contact with normal cerebral tissues.

Penicillin in Kala Azar

In the available literature to date there appears to be no record of the effect of penicillin in leishmaniasis, and as a supply of the drug has recently become available it was decided to try its action on two cases of kala azar. Both cases were regarded as clinically typical and fairly severe, and neither had previously received any kind of treatment. The following short notes illustrate the patients' conditions before and after treatment.

Case (1). Male, twenty-two years, admitted to Gedaref Hospital on 2.5.45 seriously ill with a history of seven days fever (his condition suggested he had been ill for a much longer period), and clinical dysentery.

Clinical Notes : Spleen 1 F.B. (finger's breadth below costal margin). Liver 3 F.B. Spleen and lymphatic gland smears positive for *Leishmania donovani.*
Blood Count : R.B.C., 3,000,000 ; W.B.C., 3,000. Diff. count, P 57, L 31, L.M. 12 E.O. Repeated blood films negative for malaria and other parasites.
Fæces contained blood and mucus ; no *Entamœbæ histolytica* were found. Urine normal.

After some days rest and treatment for bacillary dysentery his condition improved considerably. Penicillin treatment commenced on 21.5.45 and continued until 29.5.45. During treatment he developed an attack of malaria, and M.T. parasites were present in blood (23.5.45). The malaria was controlled by quinine. The temperature chart was complicated by the malaria, but when this was treated the temperature still continued swinging with no sign of diminution (ranging from subnormal to 104° F.). Liver and spleen were unaltered and there was no sign of clinical improvement. On 31.5.45, spleen and gland smears still positive.

Case (2). Female, aged forty, admitted on 14.5.45 complaining of fever for one month.

Clinical Notes : General condition, fair. Spleen, 3 F.B. Liver, 1 F.B. Spleen and gland smears, positive for *Leishmania donovani.*
Blood Count : R.B.C., 3,400,000 ; W.B.C., 4,000. Diff. count, P 65. Lymph 29. L.M. 6 E.O.
Repeated blood films negative for malaria or other parasites.
Fæces and urine normal.

Treatment commenced on 21.5.45 and continued until 29.5.45. During treatment the temperature showed no signs of diminution, ranging between normal and 104° F., and the general condition appeared to be deteriorating. There was no appreciable change in the blood counts and no diminution in size of the spleen and liver. On 31.5.45 spleen and gland smears still positive.

Treatment : 20,000 units of penicillin in normal saline (4 c.c.) were given intramuscularly three-hourly until a total of 1,500,000 units was reached. There were no complaints of pain or reaction. To avoid any mistake in times of administration or dosage, all injections were given personally by one of us (M. H. S.), the course of treatment, dosage and times of administration being identical for both patients.

Comments : The results were a complete failure, and there was no evidence that the course of the disease in either patient was influenced in any way. On the contrary, the condition of the second patient deteriorated, while the first patient developed malaria during the course.

It is of course well known that Sudan kala azar, as compared to the Indian disease, is far more resistant to any kind of drug, and the possibility must be admitted that much larger doses with continuous administration might have had some influence on the course of the disease. At the moment, it can only be said thay there is no evidence in favour of such a suggestion, and either repeated or continuous administration has serious disadvantages when treatment has to be carried out in a small hospital without a specially trained staff.

A Medium for Mounting Parasitic Helminths

This medium is an aqueous one, and gum arabic forms its basal element. It is clear and of a suitable refractive index for mounting stained helminthic parasites. Carmine-stained specimens mounted in this medium show no deterioration or discoloration. Above all, the medium has great tolerance of water ; in fact, no dehydration and clearing is required before mounting specimens in it.

Chemicals : Hung's Solution I*		
	Gum arabic	8 gm.
	Distilled water	20 c.c.
	Chloral hydrate	80 gm.
	Glycerine	12 c.c.
Hung's Solution II*		
	Gum arabic	20 gm.
	Distilled water	20 c.c.
	Chloral hydrate	17 gm.
	Glycerine	3 c.c.

* Dedicated to Dr. See-lu Hung, under whose guidance this medium was worked out.

In preparing the solutions, the gum arabic is first dissolved in the distilled water, then the other chemicals are added in the order given.

Procedure : The helminth is fixed and stained in the usual way. Having been destained, the material is washed in 70 per cent alcohol or in distilled water. Then it is transferred directly into solution I for one to two hours according to the size of the specimen ; material remaining in the solution I is not injured. Finally it is mounted in solution II. Within two days, the mounting medium surrounding the margin of cover glass becomes solidified, and in two weeks it becomes quite hardened.

Some worms, such as *Fasciola hepatica, Fasciolopsis buski, Echinostoma revolutum, Clonorchis sinensis, Metagonimus yokogawai, Echinococcus granulosus, Dipylidium caninum, Diphyllobothrium mansoni, Taenia crassicollis, Taenia solium, Ancylostoma duodenale, Necator americanus, Enterobius vermicularis* have been mounted satisfactorily in this medium.

THIS interesting communication directs attention to the great difficulty experienced by most workers in making really satisfactory and permanent preparations of nematodes. The Hung's solution described above resembles in composition Berlese's well-known medium for mounting small insects and small arachnids. The formula of this is given by Bolles Lee[1], as follows: Water 20 c.c., chloral hydrate up to 160 gm., gum arabic 15 gm., glucose syrup 10 c.c., acetic acid 5 c.c. On the same page Bolles Lee gives the following formula which is, it is stated, used in British and other museums (its origin is unknown): distilled water 50 c.c., gum arabic 40 gm., glycerin 20 c.c., chloral hydrate 50 gm. Dr. P. Tate of the Molteno Institute, Cambridge, reminds me that formulæ for other gum-chloral media exist, some of which contain cocaine hydrochloride, presumably put in to narcotize living small insects and arachnids. An example of these is the medium of G. Faure[2] mentioned by M. Langeron[3], who gives the following formula for it: distilled water 50 c.c., gum arabic 30 gm., chloral hydrate 50 gm., glycerin 20 c.c., 0·5 gm. cocaine hydrochloride being added when living animals are being mounted. References to methods used for the mounting of nematodes parasitic in plants will be found in "Plant Parasitic Nematodes", by T. Goodey (Methuen, London).

A gum-chloral medium is used by H. L. Ratcliffe[4] for the mounting of adult nematodes (hookworms and small nematodes) and the eggs of *Enterobius vermicularis*. A concentrated suspension of the eggs of this species in neutral formalin is passed through a series of bottles containing dilutions of gum-chloral in 10 per cent formalin, beginning with a 10 per cent dilution and rising by 2 per cent increases in strength until the eggs are suspended in pure gum-chloral. The process takes two months. Ratcliffe recommends it also for insects (including their larvæ and pupæ) and small arachnids.

D. Minckler[5] gives a method for clearing, in less than three days, adult *Enterobius vermicularis* for class study. The nematodes are fixed in 10 per cent formalin and the formalin is washed out for several hours in running water. The nematodes are then put in three changes of dioxane, each change lasting one hour. They are then put in carboxylene (phenol 25 c.c., xylene 75 c.c.) for twenty-four hours and then three changes of neutral xylene lasting a few minutes each, and mounted in damar dissolved in xylene. The nematodes are handled in a small bottle, the fluids being decanted. They adhere to the sides of the bottle, so that this is drained after each change by setting it mouth downwards upon filter paper. The nematodes are removed for final mounting by a large-calibre medicine dropper. The nematodes acquire a tan or yellow colour in various parts, but the nerve ring is not shown.

T. N. Tahmisian[6] gives a method for mounting hookworms without the opacity which is usually experienced when they are put into balsam. This has been attributed, he says, to imperfect dehydration and to exposure to air between clearing and mounting, but shows that this is not so. When he dehydrated carefully and cleared in xylene or toluene and then floated balsam over the clearing oil to prevent the access of air, 90 per cent of the nematodes were still opaque. He noted that those which cleared were always ruptured ones. He therefore partially dehydrated them in 70 per cent alcohol and then pierced the cuticle with a fine needle under the dissecting microscope. The nematodes were then further dehydrated, cleared and mounted without difficulty. He says that, when the cuticles of opaque nematodes were pierced, gas could always be expressed from them and that then they would clear. He believes that the balsam causes a rapid exosmosis of the clearing oil, so that gas forms under the cuticle and causes opacity.

There are, of course, other methods of mounting nematodes, such as treatment of them with lactophenol (see Bolles Lee, "Microtomist's Vademecum"). This is very useful for diagnosis, but preparations cleared with it are not suitable for permanent use. It seems probable that work now being done in Cambridge by Dr. Trim and at Newcastle by Prof. A. T. Hobson on the permeability of the nematode cuticle may eventually indicate methods of preliminary treatment of the nematode cuticle which will make permanent preparations of them much more satisfactory. Meanwhile it would be valuable to know of other methods which individual workers may have found satisfactory for making permanent preparations of either trematodes, cestodes or nematodes.

Production of Skin Burns by Hot Gases

THE chief factor determining the time taken to produce a burn of given severity will be the rate of heat transfer from the hot gases to the skin. Other factors such as individual variation in the skin and its condition at the time, for example, sweating, will also play their part. Thermal conduction from the skin surface into the deeper tissues is a complex phenomenon, but a simplified model leads to interesting conclusions.

If we treat the corium as a single region of reasonably uniform temperature from which heat is conducted away into the deeper tissues, that is, across or through the fatty layer when present, at a rate proportional to the elevation of its own temperature, then $d\theta/dt = Q/\rho l s - A\theta$, where Q is the rate at which heat is transferred across the epidermis into the corium from the hot gases, θ is the rise of temperature (above normal) in the corium the thickness of which is l, density ρ and specific heat s; t is the time and A a constant.

Integrating and putting $\theta = 0$ when $t = 0$,

$$t = -\frac{2\cdot30}{A}\log_{10}(1 - A\theta\rho ls/Q),$$

treating Q as a constant independent of θ, which will be justifiable while θ and the temperature difference across the epidermis are small compared with the difference between the temperature of the hot gases and skin temperature.

If a temperature rise of θ' in the corium is necessary to produce a burn of given severity, then Q must exceed $A\theta'\rho ls$ or no such burn can be produced. The total absorbed heat, H, required to produce the burn is Qt', which has a minimum value of $\theta'\rho ls$ when Q is very large.

According to recent work[1], a temperature of about 50° C. must be reached in the corium if irreversible effects leading to œdema and scabbing, that is, second-degree burns, are to occur. This corresponds to a value of θ' for such burns of about 15° C. The thickness of the corium is variable, but 1–2 mm. is average, the ventral surfaces being the thinner. Both the density and specific heat may be taken as approximately unity. Hence for burns of the ventral surface of the forearm, the value of the factor $\theta'\rho ls$ should be about 1·5.

Gas temperature (° C.)	Velocity of flow (ft.p.m.)	Q* (Cal./sec./cm.^{2})	Efficiency of thermal transfer (per cent)	H (cal./cm.^{2})		t' (sec.)	
				obs.	calc.	obs.	calc,
150†	25	0·10	35	>6	–	>60	–
200†	25	0·133	35	2·5	2·7	15–20	20
1100‡	1000	3·6	9	1·4	1·5	0·4	0·44

* Measured by the rate of temperature rise of a copper block when in similar position as the forearm. This assumes the surface coefficient to be similar for skin and metal at similar temperatures. That the epidermis is a poor conductor does not significantly affect this assumption, since its thermal capacity is negligible, and the temperature differences across it necessary to produce these rates of heat transfer are small compared with the differences of temperature between the hot gases and the skin. Under other conditions, for example, burning by contact with relatively low-temperature objects, the conductivity of the epidermis may become of major importance.

† From 1 cm. diam. jet.

‡ Large flame.

The data in the accompanying table represent a small group of nine second-degree burns of the ventral surface of the forearm of three subjects; the burnt area was about 2 cm. in diameter in each case. No burns were produced when Q was less than 0·10 cal./sec./cm.^{2}:

that is, $A\theta'\rho ls \simeq 0\cdot10$ and $A \simeq 0\cdot067$.

Hence the time taken under these conditions to produce a second-degree burn,

$$t' = 34\log_{10}\left(\frac{Q}{Q - 0\cdot10}\right).$$

The calculated values of H and t' in the table are derived from this equation and are in good agreement with the experimental figures.

Absolute and Differential Light Sensitivity of the Dark-adapting Eye

THE lack of correlation between the absolute light threshold of the dark-adapted eye and the 'ability to see in the dark' has been currently attributed to psychological factors; but little attention has been given to the behaviour of contrast sensitivity, despite the fact that vision at low illumination depends largely on the perception of differences in brightness. In particular, the possibility of variations in contrast sensitivity independent of variations in the absolute threshold does not seem to have been investigated, although the occurrence of such variations seems likely from the observations of Edmund and others[1,2].

Comparison also of the generally disappointing data on variations in the absolute light threshold of the dark-adapted eye in supposedly vitamin A deficient and non-deficient (or treated) subjects with the data on variations in contrast sensitivity as observed by the Scandinavian workers[1,2], suggests that the latter yield more significant differences. However, no reference directly relating the two functions, or adequate data allowing of direct comparison, could be found in the literature.

We have carried out a comparative study of the absolute and differential threshold of the dark-adapting eye in selected subjects with 'good' and 'poor' night vision respectively, and our observations indicate first, that, in observers with identical light-threshold recovery curves, marked differences in contrast sensitivity occur, and appear to be related to their 'ability to see in the dark'; secondly, treatment of the 'poor' observer with vitamin A together with brewers' yeast produced a striking improvement in contrast sensitivity with little effect on the light threshold.

The instrument used was the new Crookes's standard adaptometer[3], the only modification being that the test object was replaced by black or grey arrows on a fully transparent background. The curves shown here were obtained, after initial light adaptation to 750 ml. for five minutes, by recording the time required in the dark to recognize the position of a rotatable grey or black arrow on a bright ground, the brightness of which was reduced in steps. The following contrasts were used: C_1, 7 per cent; C_2, 20 per cent; C_3, 34 per cent; and C_4, 100 per cent. A curve thus obtained with a 'black' figure on a bright ground is practically identical with one obtained using a bright figure on a black ground and, with a relatively large and simple figure, is closely approximate to the recovery of the absolute light threshold. A simple figure was chosen as it objectivates the response and appears to control the part of the retina used. A remarkable reproductibility was obtained without a fixation spot[3,4]. There was thus freedom for using the most suitable part of the retina, which was parafoveal for the lower rod range; the observer was advised to facilitate perception of contrast by continuous small movements of the eye. Observation was binocular with natural pupils, the distance between eye and test object being 60 cm., the test field and the smallest detail of the arrow having a visual angle of 7° and 1° respectively. The curves representing the visibility of the lower contrasts are averaged from repeated tests, their number being indicated in brackets. (These curves describe the outer envelope of adaptation curves which are not smooth, but actually fluctuate.)

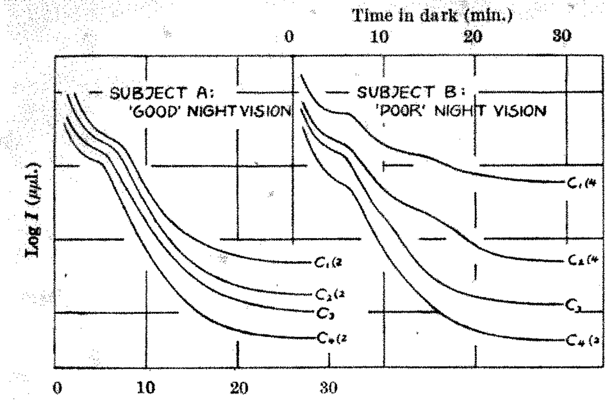

Fig. 1. RECOVERY OF CONTRAST SENSITIVITY IN TWO SUBJECTS WITH 'GOOD' AND 'POOR' VISION RESPECTIVELY.

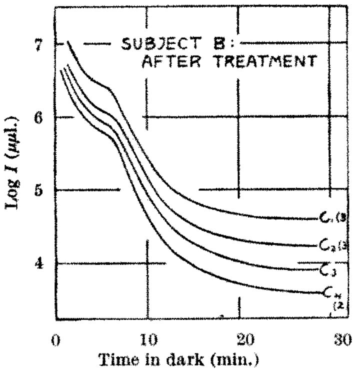

Fig. 2. SUBJECT B. FOLLOWING TREATMENT.

Fig. 1 shows a typical set of observations. Fig. 2 shows the changes in the 'poor' observer following treatment for 10–14 days, consisting of daily administration of 33,000 I.U. of vitamin A (Crookes's vitamin A concentrate) and about 10 grams of dried brewers' yeast ('Aluzyme') kindly supplied by Messrs. Phillips Yeast Products, Ltd. A second dose of vitamin A was given on the day of the tests 3–7 hours before the test.

Psychological factors undoubtedly play a part in night visual capacity[5,6]; however, complaints about poor night vision in subjects having a normal absolute light threshold should not be tacitly attributed to such factors without information concerning contrast sensitivity. It also seems likely that the latter may reflect more sensitively the influence of nutritional, metabolic and presumably also nervous factors than variations in the light threshold. It may, in fact, under the experimental conditions herein described, represent the only demonstrable change in visual sensitivity.

Our thanks are due to Messrs. Crookes Laboratories for the loan of the adaptometer, to Mr. R. B. Morris from Kodak Research Laboratory for help and advice, and to Mr. A. Rugg-Gunn for his stimulating interest.

Parthenocarpic Production of Tomato Fruits

RECENT work at Long Ashton has shown that a number of chemical compounds, when suitably applied, will induce the parthenocarpic production of tomato fruits[1]. Their effectiveness has varied between 2-4 dichlorophenoxy acetic acid which can be used at 1 p.p.m., to that of *beta* naphthoxyacetic acid which is used at 60 p.p.m. The use of the latter substance on a commercial basis is now possible, and I have used it in commercial greenhouses in 1945 to 'set' bottom trusses which had failed owing to unusual weather conditions. In one instance a natural set of 25 per cent was raised to 97 per cent by a single application.

Many of these substances, however, have marked 'formative effects' when used at relatively high concentrations[1], and a number of symptoms suggestive of virus diseases have been induced in this way[1,2]. This property is now being used in extreme measure in the so-called selective weed killers[3,4,5].

Two completely new lines of investigation have recently been opened up in experiments at Long Ashton to induce parthenocarpy in tomatoes. The first is in the use of synthetic animal hormones of the œstrogen type, the second in the use of crude extracts of tomato flowers.

Recent developments in animal hormone physiology have shown that certain substituted stilbene compounds are more effective œstrogens then the naturally occurring substance. Preliminary trials on tomato have shown that 4-4′ dihydroxydiethyl stilbene (stilbœstrol) will cause parthenocarpic development of tomato fruits within the concentration range 50–100 p.p.m. Hexœstrol, which is the hydrogenated stilbœstrol, has also been shown to be active in this direction. These observations are of considerable theoretical interest since the latter substance is a fully saturated compound and does not contain a carboxyl group. By further substitutions within this molecule, it may be possible to provide a chemical theory for some of the work now in progress.

The second line of development is no less important. During this work large numbers of tomato flowers were removed just prior to anthesis. These were stored in the laboratory in a litre beaker until it was nearly full. These flowers were then extracted with ether under a reflux condenser. The dried ether extract was taken up with 5 ml. of absolute alcohol and diluted to 100 ml. with water, when a dense cloudy suspension of unknown concentration was obtained. Portions of this suspension were further diluted to ¼ and ½ strengths respectively, thus giving three concentrations. All these proved active when applied to the tomato. 5 ml. of 11 per cent ester salts per litre of water was added to all sprays in order to provide adequate wetting properties. The most concentrated solution induced 100 per cent set when applied to flowers which had been deflorated fourteen days earlier. Appreciable development of the fruits was noticeable three days after application and in this respect the extract of tomato flowers compared favourably with beta naphthoxyacetic acid. A second batch of flowers similarly extracted yielded an extract which was equally active. It is hoped in due course to obtain sufficient material to provide for biochemical investigations of the active substances in the flower extract.

These observations suggest an important field for investigation into problems of fruit setting and development of tree fruits, and may have important applications in orchard practice in relation to problems of pollination and sterility.

In similar experiments with apples and pears, only limited success has so far been achieved. A severe frost occurred on April 30–May 1, 1945, by which time apple and pear fruits had set and commenced to swell. The frost killed the embryos and blackened the centres of the fruits. A number of trees of apple and pear bearing crops of these frosted fruits were sprayed on May 8 with a mixture of growth-promoting substances known to be effective on tomato. Conference pear and Miller's Seedling apple responded to the spray, and at the time of writing all treated fruits are still on the trees and some show appreciable swelling. Cox trees sprayed at the same time with the same mixture did not respond and all the fruits fell off, as was also the case with the untreated trees of Miller's Seedling. It is still doubtful whether the treated fruits of Miller's Seedling will develop to full size or maturity, but it is of interest that such severely damaged fruits have been prevented from falling, and it seems reasonable to expect that in further experiments suitable materials will be found which will be as effective on apples and pears in inducing parthenocarpy as *beta* naphthoxyacetic acid is on tomato.

Grateful acknowledgment is made to Dr. S. J. Folley, of the National Institute for Research in Dairying, and to Messrs. Boots, Ltd., for the synthetic œstrogens used in these experiments.

Neutron-Proton Scattering at 8·8 and 13 MeV.

THE experimental work of Champion and Powell[1] on neutron-proton scattering at 8·8 and 13 MeV. gives, essentially, two new results: (1) the angular distribution, as given by the best smooth curve, is not exactly isotropic as is generally expected for particles of wave-lengths long compared with the dimensions of the system; (2) there is some evidence for a high-order fluctuation in the intensity.

Champion and Powell suggest (*op. cit.*, p. 84) that the general trend of the distribution can be due to a small p-component in the scattered wave. However, the intervention of forces deriving from potentials of the type

$$S_{12} = ({}^1\vec{\sigma}\vec{r}_{12})\,({}^2\vec{\sigma}\vec{r}_{12})\,.\,f(r_{12}), \quad . \quad . \quad (1)$$

suggested by the existence of the quadrupole electric moment of the ground-state of the deuteron[2], gives rise, already in the lowest-order scattering wave, to a mixture of S and D states, therefore leading—even in the first approximation—to an anisotropic scattering.

Rodrigues Martins[3] has investigated the influence of the coupling (1) on the angular distribution of the triplet (${}^3S + {}^3D$) scattering. Following the general lines of his paper, it can be shown that the angular distribution of the lowest scattering is given by

$$I(\theta) = 1 - 1{\cdot}19\,|C_2| \cos\delta\,.\tfrac{1}{2}(3\cos^2\theta - 1) + f(\theta).|C_2|^2 +, \quad . \quad . \quad (2)$$

where C_2 is the scattering coefficient of the d-wave (taking $C_0 = 1$), and δ is its phase-shift.

Neglecting the quadratic terms, we obtain the general trend of the distribution (referred to the centre of mass of the system); determining the factor $|C_2| \cos\delta$ so that the mean quadratic error with respect to the curves of Champion and Powell be a minimum, we obtain the values $- 0{\cdot}11$ for the 8·8 MeV. neutrons group, and $+ 0{\cdot}14$ for the 13 MeV. group. Drawing the curve, it is seen that the intervention of potentials of the type (1) produces a remarkable anisotropy in the angular distribution. According to the formulæ given by Rodrigues Martins (due to eventual resonance with compound levels), the values of $|C_2|$ are of the order of 1/10 and are thus sufficiently in agreement with the values of $|C_2| \cos\delta$ as obtained above.

On the other hand, the fluctuations suggested by Champion and Powell cannot be explained by the intervention of forces of the type (1). As a matter of fact, the amplitude of these fluctuations exceeds considerably the value of the quadratic terms of (2); and their frequency would require the inclusion of spherical waves of very high order. Therefore, if these fluctuations should be found to be real, it would be hard to explain them by any physical picture.

Supposing, further, that all the forces acting are of the exchange type, the potential (1) would have to be replaced by[4]

$$R_{12} = \tfrac{1}{2}(1 - {}^1\beta\,{}^2\beta)\,({}^1\vec{\alpha}\vec{r}_{12})\,({}^2\vec{\alpha}\vec{r}_{12})\,.\,f(r_{12}) \quad (3)$$

The amplitudes of the scattered waves remain, then, essentially the same as in the foregoing case, at least in Born's approximation.

Time Dependence of Interfacial Tension and Density in Solutions

DR. A. F. H. Ward and L. Tordai[1] have described experiments showing changes of interfacial tension with time in solutions. There is no mention made whether in these experiments density changes also could be observed.

I have investigated a number of systems in which the interfacial tension changes in time. The most remarkable feature of these experiments was the time dependence of some other properties, and densities in particular. Densities can be easily measured to six decimal places. I observed changes in the third decimal as a rule. Changes in densities were observed irrespective of whether the experiments were conducted uninterruptedly, or portions taken out for individual measurements.

Before equilibrium is reached, the physical properties and densities in particular fluctuate all the time, and eventually they become stabilized and acquire definite values. Similarly, F. F. Nord[2] with collaborators has described volume changes in sodium oleate as a function of time.

These facts cannot be interpreted as surface phenomena, but must be attributed to changes in the bulk of solutions[3].

Occurrence of Boron Phosphate in Fireside Deposit from an Economizer

IN a recent communication in *Nature*, Rafter[1] has directed attention to the presence of appreciable proportions of boron in samples of New Zealand coal ashes.

In this connexion it may be of interest to note the presence of a comparatively large proportion of boron phosphate in a deposit recently examined here. This deposit was one of several typical deposits from the fireside of economizers and boiler tubes of certain high-pressure boiler plants which were examined in 1942 and 1943; the work was carried out at the request of the British Coal Utilisation Research Association acting on behalf of the Boiler Availability Committee sponsored by the Central Electricity Board.

The method of separating deposits taken from the fireside of economizers and boiler tubes into convenient fractions has been suggested by B.C.U.R.A. It is as follows: the sample is powdered, extracted by boiling water, then by 10 per cent aqueous nitric acid and finally the insoluble residue is analysed. The insoluble residue prepared in this way from the deposit removed from an economizer of a high-pressure boiler had the following composition:

SiO_2	50·93%	$K_2O + Na_2O$	1·92%
Fe_2O_3	8·7	$CaO + MgO$	0·82
Al_2O_3	4·16	P_2O_5	17·7
B_2O_3	7·6	SO_3	1·78

Loss on ignition, 8·04 per cent.

There was negligible loss of phosphoric acid when the material was boiled with water or with 10 per cent nitric acid. It was therefore probable that the phosphoric acid was not combined with the metallic oxides. A search was next made into the possibility of its being combined with silica or with boric oxide.

Comparatively stable silicyl phosphates have been prepared[2] and their X-ray powder patterns described[3]; the X-ray powder pattern of the insoluble residue from the economizer deposit did not correspond with that in ref. 3 or with that of the silicyl phosphate which we synthesized by the method given by Hautefeuille and Margottet.

On the other hand, boron phosphate made as described by Vogel[4] gave a pattern corresponding exactly with that produced from the insoluble residue. This pattern agrees with that determined by Schultze[5] and with that set out in the Index of X-Ray Diffraction Patterns published by the American Society for Testing Materials (Card 1301). Boron phosphate is therefore a major constituent of the insoluble residue from the economizer deposit; it amounted to about 4½ per cent of the particular sample of deposit which we examined. Unfortunately, it is not possible to relate this occurrence of boron phosphate to the fuel from which it was derived, because during the time the deposit was being formed, the fuel burned in the grate was drawn from a wide variety of sources.

The Hazel Period in the Post-Glacial Development of Forests

POLLEN analysis shows the well-known hazel-maximum, especially in Central and Western Europe. In certain horizons hazel pollen is so frequent that there must have existed real hazel-scrub forests. This hazel period has been assigned to the beginning of the post-glacial warm period, and coincides with the mesolithic culture period (see, for example, Firbas[1]).

The reason for this high frequency of hazel pollen is, according to Firbas, difficult to understand to-day. This is shown too by the interesting attempt of Erdtman[2] to explain the apparent pollen frequency by modalities of sedimentation and preservation of hazel pollen.

Climatic changes, such as those in humidity, should not have been very important, according to Salisbury and Jane's[3] determinations of widths of annual rings.

I would not attempt to suggest a possible explanation for the problem, if I had not observed, during residence in Brazil, the great transformations in vegetation caused by natural or artificial fires. Modern ecology agrees that fires made by primitive man, to free land for the hunter and the cultivator, have swept over very large areas. It is probable that prehistoric man acted in the same way. Fire has a selective action among the plants, according to their capacity to survive it. *Corylus* seems to be fire-resistant. This is emphasized in the very interesting description that E. Chavannes[4] gives for Wisconsin: ". . . Names of a Richwood, Glenwood, Woodland type appear frequently, as do several forest townships in the north and east. Scrub vegetation characteristic of areas undergoing encroachment is described in Hazel Green, a village name referring not to a pioneer's sweetheart, but to a condition commonly found in burned-over woodland. After ground cover and trees were destroyed by recurrent prairie fires, hazel brush sprang up thickly, persisting through the fires by virtue of a sturdy root system, flourishing as a scrub between destructions."

If during the Mesolithic period the same methods of using fire were practised, the existence of such prevalent hazel vegetation would not be unexpected; in any event there is a certain concordance in the maps of the distribution of the hazel maximum in the boreal period, for example, that given by Erdtman for Europe, and the distribution of the Campignien culture period, as generally indicated by prehistorians.

In this connexion it is interesting that hazel in North America is seldom if ever mentioned by authors from that country (for literature see Sears[5]). Detailed studies on the connexion of the hazel period with the prehistoric cultures would probably be interesting.

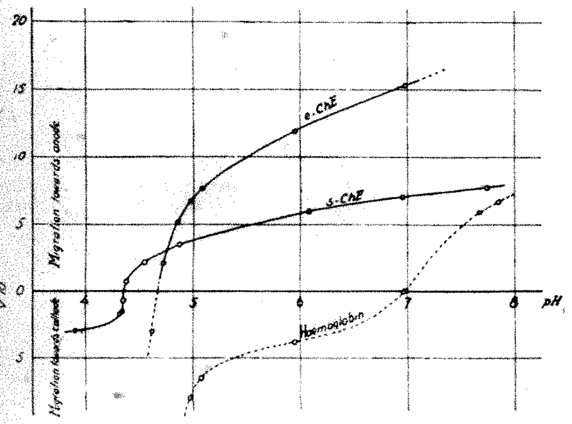
Choline Esterases

A DEFINITE proof that two distinct choline esterases really exist has been sought by Bader *et al.*[1], who call for an "electrophoretic or closer elementary analysis". I have reported such an analysis in a recent paper[2], which has obviously not reached these authors.

I have shown that a true chemically established difference exists between the acetylcholine-hydrolysing enzymes in horse blood serum and red blood cells. Cataphoretic investigations show that a large difference exists between the rates of migration of the two enzymes in the electric field. This is shown in the accompanying figure (for details, see the original paper). Furthermore, erythrocyte choline esterase seems considerably more sensitive to pH than serum choline esterase.



It may thus be definitely stated that the choline esterases from blood serum and erythrocytes are not identical.

The next question to be decided is whether choline esterase from blood cells is identical with the enzyme in brain. Work by Canadian and Swiss schools have shown that this is in fact the case. I am at present engaged in an attempt to prove this chemically. Preliminary examinations have shown the permanence towards pH-changes of the brain choline esterase (ox) is much the same as that of erythrocyte choline esterase. Thus the brain choline esterase is wholly destroyed at $p\mathrm{H} \approx 4 \cdot 7$ and has lost 40 per cent of its activity at $p\mathrm{H} \approx 6$. The corresponding figures for the erythrocyte choline esterase are $p\mathrm{H} \approx 4 \cdot 5$ and 50 per cent at $p\mathrm{H} \approx 5$, for serum choline esterase $p\mathrm{H} \approx 2$ and no loss of activity at $p\mathrm{H} \approx 6$.

In a letter addressed to Dr. Zeller in Basel in October 1943, I expressed the opinion that it is highly probable that we must henceforth take into consideration even more types of choline esterase. Many facts suggest this. Thus the enzyme in mollusc hepatopancreas and choline esterase in the venom of *Cobra* have not the same properties as either of the two types mentioned above. Indeed we know very little about the specificity of choline esterase in invertebrates. An investigation in this sphere is being planned.

I largely agree with Richter and Croft[3] in their statement that "it would appear more accurate to describe the choline esterases as a group of enzymes showing considerably divergent properties rather than to regard choline esterase as a single entity".

A Theory of Telepathy

IN his recent review[1], Dr. E. J. Dingwall includes a quotation which refers to an alleged disintegration of memory in trance personalities.

This should not be considered without reference to the natural disintegration of memory throughout life. If any personality is observed through life from the time of his graduating or passing professional examinations, there is a gradual dispersal of the knowledge gained, in spite of the fact that his environment is such that the knowledge would be of considerable value. If we assume a continuation of this process after the death of the body, then, in view of the fact that the new environment no longer demands retention of earth-memories, it is surely remarkable that they persist as long as they do.

Custody of Uranium

MANY of us have used specimens of pitchblende as demonstration pieces, perhaps to take autophotographs during the course of a lecture. The newly disclosed potential menace of a pound weight of such material brings with it a warning that those entrusted with the custody of any uranium-bearing minerals should take their obligations seriously; from careless hands uranium might pass to unscrupulous ones.

RESEARCH ITEMS

Low-Temperature Limits of Life

The temperature of water inhabited by living organisms is assumed not to fall below $-3\cdot3°$ C. In the salt lakes of Kazakhstan, however, water becomes cooled well below that limit while still remaining liquid, and plankton investigations by S. A. Zernov and O. I. Schmalhausen (*C.R. Acad. Sci. URSS.*, **44**; 1944) have shown that motile algæ, *Pyramimonas* sp. and *Dunaliella* sp., are able to survive winter in salt water cooled down to $-5°$ C. and even $-7\cdot75°$ C., remaining fully active. Various other algæ of the genera *Oscillatoria*, *Nodularia*, *Glœotila* and *Botryococcus* also appear to be able to survive such temperatures. Under experimental conditions, both *Pyramimonas* and *Dunaliella* were found to survive and swim in a drop of salt water from the lake cooled down to $-15°$ C. The upper temperature limit for *Pyramimonas* was experimentally found to be $+29°$ C., and for *Dunaliella* $+42°$ C.

American Clingfishes

L. P. Schultz has subjected the American species of Gobiesocidæ to a thorough revision and described new genera and species (*Proc. U.S. Nat. Mus.*, **96**, No. 3187; 1944). The clingfishes are mostly marine, but a few species occur in freshwater streams, a short distance above brackish water, clinging to the stones. *Gobiesox cephalus* Lacepède is one of these and occurs in freshwater streams of northern South America and Central America on the Atlantic side, and there are four other American species. A key to the genera and species of the American Gobiesocidæ is given, including nine genera and twenty-four species, and a table of counts made on the dorsal fin rays, anal fin rays, pectoral fin rays above attachment of gill membrane, and pectoral fin rays.

Mutations in Bacterial Virus

S. E. Luria (*Genetics*, **30**, 84; 1945) shows that α and γ, the two viruses of *Escherichia coli*, produce by mutation new strains which are able to attack strains of the bacterial host which were resistant to the original virus strains. Mutation in bacteria and in these viruses in respect of resistance is specific and is generally independent; in one exceptional case a bacterial strain resistant to α and α^1 reverted to susceptibility as a result of a mutation to resistance to virus γ and γ^1. The changes in resistance are considered by the author not to be due to adaptation.

Biennial Bearing of Apple Trees

Biennial bearing, to which many apple varieties are prone, is one of the important causes of gluts. Attempts to modify this character and at the same time to provide a satisfactory thinning of the crop by the use of caustic sprays at blossom time have been made in the United States. The sprays used generally have a basis of sodium dinitrocresylate or other similar dinitro compound; but the difficulties in their use are numerous. F. S. Howlett (*Proc. Amer. Soc. Hort. Sci.*, **42**, 151; 1943) has described how the thinning effect differs with the variety and with the season, while A. B. Burrell (pp. 159–162) points out that even a single spray may result in an excessive thinning of the crop. Nevertheless the early fruit thinning (supplemented when necessary by hand thinning in June) is advantageous in that it reduces competition between fruits early in the season, and this may be one reason why sprayed trees give larger fruits than hand-thinned trees, as reported by A. V. Doren and M. B. Hoffman (pp. 182–184). A further effect of the reduction of crop in an 'on' (that is, bearing) year brought about by this treatment may be an increased initiation of fruit buds, so that blossom and fruit production in the following 'off' year (M. B. Hoffman and J. D. Van Geluwe, pp. 185–186) are both increased and the biennial-bearing habit thus somewhat, although not markedly, modified. This effect of the caustic spray may be intensified by branch ringing in the 'on' year (A. E. Murneek, pp. 163–166); but sometimes the complete removal of the crop by spraying the bloom with a caustic spray fails to induce flowering in the following 'off' year (A. E. Murneek, pp. 177–181).

Chalk-washing of Sugar-Beet in Dry Climates

Sugar-beet plants cultivated in hot, dry climates are liable to wilting. The problem has serious economic importance in some regions of the Soviet Union, such as the Northern Caucasus and Middle Asia, but ingenious experiments in chalk-washing the plants, with the view of reducing the absorption of radiant heat, carried out during 1932–41 (Kolossov, *C.R. Acad. Sci. URSS.*, **42**; 1944), have proved that this process reduces wilting. When leaves were covered with a 10 per cent suspension of chalk in water, their transpiration decreased by 14–23 per cent; the osmotic pressure of the sap fell from 17·8 to 14·2 atmospheres; the temperature of chalk-washed leaves was reduced by 4·5° C. The yields were increased by the treatment, in the case of roots by 13–14 per cent, and in the case of seed plants by 19·7 per cent. Germinating capacity of seeds from treated plants was not affected; but their energy of growth was considerably higher and the number of shoots per seed was greater than in the controls.

Structure of the Vredefort 'Dome'

The Vredefort 'dome', situated in the northern Orange Free State and the southern Transvaal, has long been a tectonic enigma to geologists. It has hitherto been described as a nearly circular mass of Older Granite 26 miles in diameter, surrounded by concentric belts of sedimentary rocks which are overtilted and inverted through a thickness of several thousands of feet, so that they everywhere dip inwards towards the granite. The south-easterly part of the structure, however, is hidden beneath a horizontal cover of Permo-Carboniferous strata. A highly significant correction to this reading of the structure is suggested by the results of a gravimetric survey carried out by B. D. Maree (*Trans. Geol. Soc. S. Africa*, **47**, 183; 1945). Large and easily recognizable gravitational anomalies were found to exist on the sedimentary belts, and when these were traced to the covered south-eastern portion, the structure, instead of being circular, was found to have the shape of a pear, with the tapering end pointing to the south-east. The anomalies are arranged symmetrically about an axis striking 32° west of north, through the middle of the exposed mass of granite. There is no longer any necessity to postulate vertical, centripetal and evenly distributed forces to account for a supposedly circular structure symmetrical about a point. The observed overtilting of the sediments in the north-west can now be ascribed to a tectonic deformation directed superficially from the south-east, the core of Older Granite being infolded with the sediments. This interpretation is consistent with the existence of a big thrust fault at Potchefstroom. The gabbro sheets and bosses of alkali rocks of the region represent post-tectonic phases of magmatic activity. The aureole of metamorphism and a marked area of positive anomalies found over the Older Granite indicate that the great bulk of these later igneous rocks is still concealed. The survey has disclosed the high probability that a large area is underlain by the Witwatersrand System with dips that would favour mining activities. It remains for the drill to prove the possible presence of gold-bearing banket in these formations.

Nuclear Energy Generation in the Sun

THE only source of energy generation in main-sequence stars which has as yet been found to satisfy even remotely the astrophysical requirements is the Bethe carbon cycle. In this process, a helium nucleus is formed from four protons, with the emission of energy in the form of γ-radiation, the process being catalytically assisted by a carbon nucleus. Attempts at determining the internal distribution of temperature and density in the sun, on the basis of a model in which all the energy is generated by this means in a convective core surrounded by a radiative envelope, have met only with qualitative success, however. Although the hydrogen content needed to fit such a model agrees with Eddington's value of 35 per cent, and the central temperature and density are not unreasonable, use of the carbon cycle to predict the luminosity gives a result nearly 150 times the observed value. This discrepancy, however small compared with those resulting when other nuclear reactions are assumed, has undoubtedly delayed general acceptance of the carbon cycle. Now, however (*Astrophys. J.*, **100**, 347 ; 1944), N. R. Sen and U. R. Burman have developed a solar model based on Bethe's law which is much more satisfactory. With a given composition and central temperature, a series of cores is studied, each corresponding to a particular central density. Only one of these satisfies Bethe's law and the boundary conditions ; in it the central temperature is the commonly accepted value of $20{\cdot}2 \times 10^{6}$ degrees, but the central density of $45{\cdot}5$ gm./cm.^{3} is very much smaller than the value ordinarily assumed. This model gives a total luminosity within 2 per cent of the observed energy output, a mass 7 per cent larger and a radius 1·5 per cent larger than the observational values. Still better agreement with observation is predicted if minor adjustments are made in the constants used.

Surge Characteristics in Electric Transmission

IN a paper (*J. Inst. Elec. Eng.*, **92**, Pt. 2, No. 25, Feb. 1945) on "Surge Characteristics of a Three-Phase Transmission Line with Earth Wire", W. G. Hawley deals first with the data and formulæ necessary for evaluating the self and mutual surge-impedance values of a three-conductor overhead system equipped with a single earth wire. It is then indicated how these impedances may be used for obtaining the theoretical attenuation and distortion, below corona, of standard unidirectional surges. Good agreement is shown to exist between theory and experiment. Above corona, loss factors for the short surges employed are deduced from experimental results, and formulæ are given to enable the corresponding factors for any single-circuit line conductor to be found. Formulæ for determining the visual critical corona voltages of one, two or all three conductors of a system are also given, in terms of the relevant surge impedance values. Finally, several values for a typical line are included.

Over-Current Relays on Medium-Voltage Circuits

A PAPER read by A. G. Shreeve and P. J. Shipton before the Institution of Electrical Engineers reviews existing methods of protection from excess load current in medium-voltage circuits, and outlines some of the problems encountered with the wide variation of industrial applications. British Standard Specifications dealing with excess current are considered, suggestions are made to correlate them, and the main factors which determine the protection required are reviewed. Motor starting-loads, starting times, and various duty cycles are mentioned, and reference is made to faults which can be caused by the inherent characteristics of some electrical equipment. Existing basic designs of overload relays and some of the difficulties experienced with them are dealt with, and an outline is given of the effect of temperature variation on thermal- and oil-type devices, and of excess current due to lost-phase faults, together with suggestions for the type of protection required to meet various circuit conditions. The relation of equipment to both excess load – current capacity and short-circuit rupturing capacity is considered, and attention is paid to the correlation of fuses and overload relay design with the thermal rating of electrical gear in the protected circuit.

Tensile Load on Steel-Cored Aluminium Conductors

A PAPER read by E. W. W. Double in London on April 11 before the Institution of Electrical Engineers dealt with the distribution of tensile load on steel-cored aluminium conductors in relation to their temperature and sag. The main objects of the investigation were : (1) to determine the effects of temperature and tension upon the sharing of the tensile load between the steel and aluminium components of such a conductor ; (2) to ascertain whether variations in the load distribution seriously affect the normal sag and safety of the conductor ; and (3) to propose measures for ensuring that the normal sag remains unaffected after the stringing of the conductor. Tensions in the steel and aluminium at various points along typical conductors were measured by a magnetic method. The effects of load-distribution changes were also estimated by noting the corresponding variation in the elastic modulus of the conductor. Adhesion between the steel and aluminium was also examined. The results indicated that the final load distribution is determined by the rate of creep in the aluminium wires, and is independent of the stringing temperature. Although more data concerning creep are required, the tests suggested that it will be some years before creep has any marked effect. It was found that the inelastic stretch of a conductor can cause large increases in sag which far outweigh those that might result from creep. Most of the inelastic stretch was removed when the conductor was tensioned up to the maximum design load, and stressing the conductors before final stringing is therefore strongly recommended. The steel core appears to carry slightly more than its share of the total load, but since its safety and that of the conductor are not threatened thereby, no change in the British Standards Specification governing the strength of steel-cored aluminium conductors is advocated.

ASPECTS OF THE DETERMINATION OF THE STRENGTH OF MATERIALS

A MEETING of the British Rheologists' Club was held on June 16 at the Royal Aircraft Establishment, Farnborough, Hants, in the Assembly Hall, through the courtesy of the director, Mr. W. S. Farren, the subject chosen being the "Strength of Materials". Dr. W. Douglas, head of the Materials Department of the Establishment, took the chair in the absence in the U.S.S.R. of the president, Prof. E. N. da C. Andrade. For those unfamiliar with the Establishment, it may be added that it is a directorate under the Controller of Research and Development of the Ministry of Aircraft Production. It is the chief research and experimental station under the Ministry, and it is concerned in all those fields of fundamental and applied science which influence the design, construction and performance of aircraft, military and civil, and in the equipment of aircraft.

Dr. M. C. Pryor, in a paper entitled "Wood and Glue", spoke during the morning session on the molecular and micro structure of timbers used in aircraft construction, and of the micro methods employed after an accident to establish the cause of mechanical failure. The movement of micelle aggregates during deformation is accompanied by rupture with the formation of fresh surfaces between the lignin and cellulose portions in the strained and damaged areas, and these fresh surfaces can be selectively stained. Failures by compression or tension are easily distinguishable microscopically, as originally shown by W. Robinson (*Phil. Trans.*, B, **210**, 49 ; 1920). Under compression, the tracheids in the zone of failure are considerably buckled. The zones of failure, which usually are well defined, run in planes at an angle of about 45° to the compression stress. Under tension, failure develops along slip planes in the substance of the cell walls, and these local shear failures occur in isolated points where the tube wall is weak, so that the failures are scattered up and down the members over quite a wide distance, perhaps for several inches. Some of the microphotographs shown at the meeting illustrating the general behaviour are reproduced herewith.

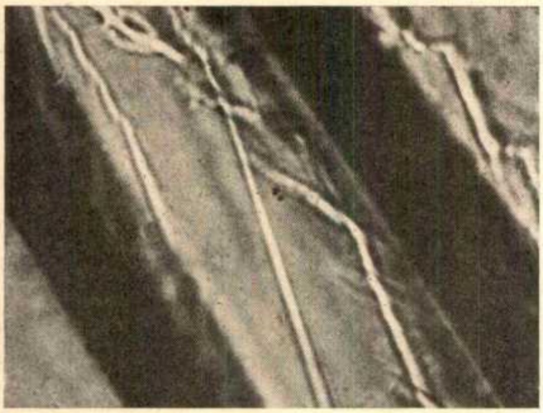

Fig. 1. TENSION FAILURE OF SITKA SPRUCE, FROM AN AIRCRAFT SPAR; LONGITUDINAL RADIAL SECTION, SHOWING PLANES OF FRACTURE. × 1,000.

Mr. C. Gurney read a paper on the "Effect of Duration of Loading on the Strength of Brittle Materials". Some brittle materials, particularly mineral glasses, are known to be subject to static fatigue, the breaking load decreasing with duration of loading; for example, experiments on an annealed soda-lime glass showed that the strength decreased in the ratio 3 : 1 when the duration of loading was increased from 10^{-2} to 10^{4} sec. It is generally accepted that the weakness of brittle materials is due to cracks, as suggested by Griffith. A likely explanation of the time dependence of strength might be the gradual spread of cracks; Griffith, after considering the energy conditions necessary for the spread of cracks, concluded that crack-spreading could not occur until a critical load was reached; at this load the crack spread catastrophically, and failure was immediate. In these circumstances, the only previous explanation of failure after prolonged loading which is consistent with general principles is damage to the surface material by atmospheric attack. If glass is rapidly broken, there may be no time for atmospheric attack of the growing surfaces of the crack, so that a relatively high strength corresponding to the uncontaminated surfaces is obtained. A number of processes by which cracks may spread, consistent with the laws of thermodynamics, were described, and a new estimate of the strength of flawless materials was given. Stress reduces the height of atomic energy barriers, and immediate failure of a uniformly stressed material will occur when the average thermal motion is just sufficient to overcome the average energy barrier. This condition is approximately that at which the latent heat of isothermal evaporation is zero.

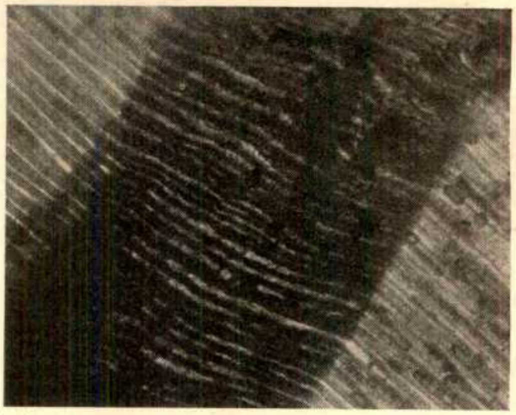

Fig. 2. ZONE OF FAILURE IN DOUGLAS FIR, STAINED WITH ZINC CHLOR IODIDE. × 60.

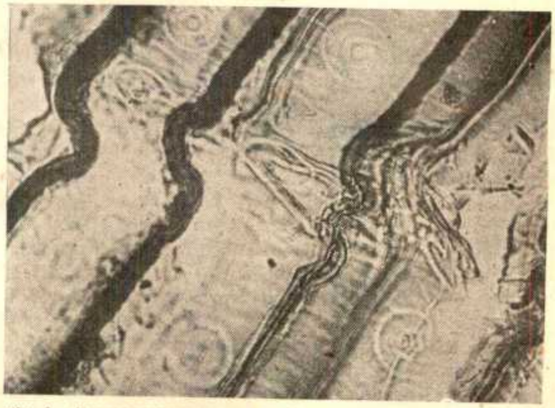

Fig. 3. COMPRESSION FAILURE IN DOUGLAS FIR, SHOWING EARLY STAGE OF BUCKLING OF TRACHEIDS. × 400.

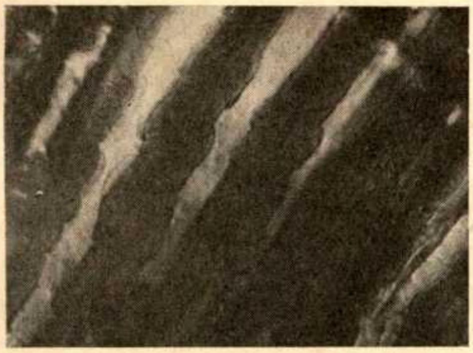

Fig. 4. Compression failure in Douglas fir, showing slip planes within the cell walls. × 650.

At lower stresses, failure is still possible, but it takes time. The stress-free vapour pressure of strong solids is extremely small, but it has been shown that the logarithm of the vapour pressure is approximately proportional to the square of the stress, so that the vapour pressure becomes appreciable at high stresses such as can occur at the end of cracks. The rate at which cracks spread by evaporation of the material has been estimated and found to be insufficient to account for the whole of the time effect with mineral glasses, tested under atmospheric conditions. In a material the atomic arrangement of which is in thermal equilibrium, increase in crack-length by splitting without atomic migrations can only occur at loads in excess of that given by the Griffith criterion. It has hitherto been thought that failure was immediate at the Griffith load, but it has been shown that, for materials having atomic constitution, the Griffith load is the lowest at which the crack may start to spread by splitting, the rate of spread being a function of the stress difference between that at the end of the crack and the maximum the material can withstand. For materials not in thermal equilibrium, the application of stress by reducing the height of energy barriers enables the approach to equilibrium to continue; and if this involves heterogeneous volume changes, internal stresses are set up which cause cracks to spread. Atmospheric attack, involving weakening of the surface material and possible solution of material at the ends of cracks—solubility increases very rapidly with stress—is likely to be an important factor in causing fracture under prolonged loading, when tests are made under ordinary atmospheric conditions.

In the discussion which followed, Dr. E. Orowan spoke on the mechanism of crack spreading and emphasized the importance of atmospheric attack. Dr. Maunder Foster mentioned the high stresses produced during grinding and their effect on reduction of molecular weight.

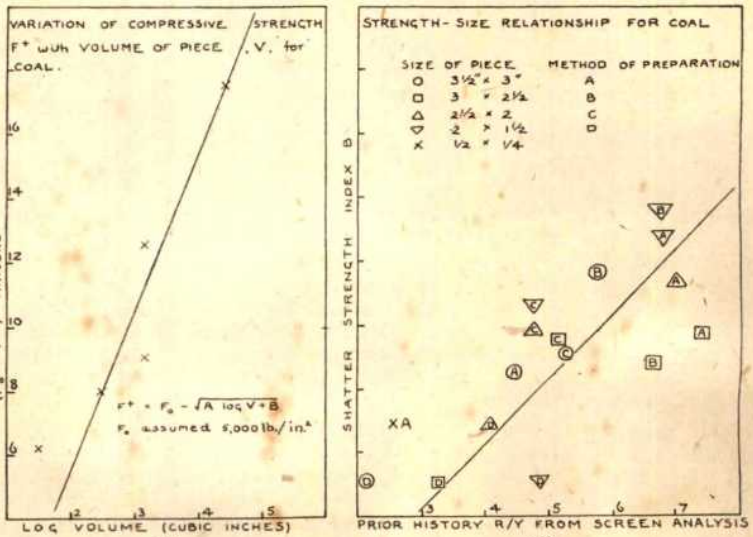
During the afternoon session, Dr. B. Chalmers, in a paper with Mr. E. R. W. Jones, on the "Application of Statistical Methods to Mechanical Test Results", gave a brief account of reasons for adopting a statistical approach to the interpretation of mechanical test results; and examples were given of significance testing, assessment of correlation and curve-fitting in relation to experimental results.

Strength tests are in general destructive, so that it is impossible to apply them to the component to be used. When they are non-destructive, the measurement is not of the property under consideration but of another property in some way related to it. In either case one requires a basis for inferring mechanical properties of the component from the known properties of the specimen tested. It was pointed out that the three reasons for doing mechanical tests are: (*a*) to provide design data; (*b*) to determine whether two or more batches of material are significantly the same in the mechanical property examined; and (*c*) to provide the basis for establishing the rheological laws for the material.

It was emphasized that, in all statements of the numerical value of a quantity, it is desirable to quote both the mean and an estimate of the scatter, based on the standard deviation.

The importance of using impersonal methods for fitting curves was demonstrated by an example in which significantly different results were obtained by various observers interpolating on the same experimental points. In conclusion, a method of presenting results of fatigue tests was shown giving the stresses below which only a stated percentage of specimens would be expected to fail. The view was expressed that this is the logical method of expressing such information in cases where the data are to be used quantitatively for design purposes.

In a written contribution, Mr. R. L. Brown, of the Coal Utilisation Research Association, continued the discussion by referring to the statistical approach and the application of the Griffith crack theory to the strength of coal. In compression tests on cubical cylinders where the load is increased slowly until failure occurs, the worst crack determines the strength. Applying Frenkel and Kontorova's work on the 'worst' crack theory to the effect of size of specimen, it is found that data for coal are well represented (Fig. 5*a*).



(*a*) (*b*)

For size x in., R = per cent greater than size (x) and Y = yield of size x, per cent per inch, in consignment from which samples for test are taken.

Fig. 5.

In shatter tests, strength can be assessed by the amount of breakage when a sample of a hundred or so pieces of coal is dropped 6 ft. on to an iron plate. Here the extent of cracks rather than the worst crack determines the strength. If it be assumed that the deformation caused by a sudden blow is elastic and that failure occurs when the strain energy exceeds a certain average value E (the value of E depends on the extent of pre-cracking and a hypothetical strain energy), then a formula can be derived for the shatter strength in terms of two factors ; first, the amount of breakage, and secondly the size distribution of the dust produced.

The size of the specimen now affects its strength in a rather different way. In Fig. 5*b* the linear relationship between shatter strength and the size distribution of the consignment from which the coal for test is taken (R = per cent oversize, Y = yield in per cent per inch) indicates that the shatter strength is proportional to the difference of the size subjected to test from the biggest material present (which is approximately R/Y) the departure being in the sense that the strength increases with decreasing size. This linear relation has been derived theoretically and will be published shortly.

The linear relationship shown in Fig. 5*b* is interesting in that it enables the strength of the coal to be predicted from its previous history, so far as this is shown by the size distribution of the consignment. In other words, the handling of coal results in invisible breakage (or cracks and loss of strength) and visible breakage, and these two forms of breakage are balanced as shown.

A CONSTITUTIONAL SYNTHESIS OF CHONDROSAMINE

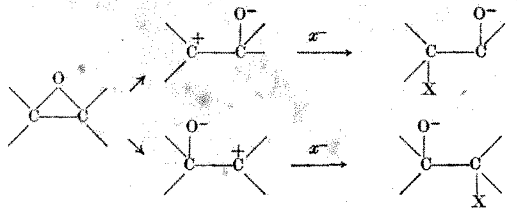
By Drs. SYBIL P. JAMES, F. SMITH, M. STACEY and L. F. WIGGINS

Chemistry Department, University of Birmingham

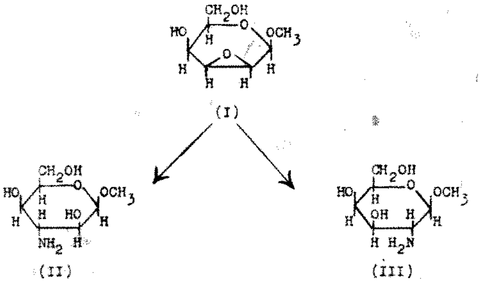
THE naturally occurring *d*-aminohexoses, glucosamine and chondrosamine, have long been known and are widely distributed in biologically important polysaccharides[1]. Any precise configuration of these substances, however, eluded chemists until 1939[2], when a derivative of glucosamine was synthesized by a method which proved conclusively that this amino-sugar was configurationally related to glucose, a conclusion confirmed independently by X-ray crystallographic methods[3]. The configuration of chondrosamine or its derivatives, however, has not been elucidated hitherto. It is generally believed that chondrosamine, the amino-sugar of cartilage[4], is related to *d*-galactose, with its amino-group on the second carbon atom[5], and it can certainly have only one of two configurations, namely, that of *d*-galactose or *d*-talose, since the amino-sugar can be transformed with loss of its amino-group into galactose phenylosazone[6,7].

The problem of deciding the configuration of chondrosamine has engaged our attention for some time, and by application of the technique of anhydro-ring formation and scission[2], we are now able to report a synthesis of chondrosamine by a procedure which determines its constitution.

The method is dependent upon the discovery[8] that anhydro-rings of the ethylene oxide type formed by the alkyl-oxygen fission of suitable esters (*p*-toluene sulphonates) undergo ring-scission in both the possible directions, that is, by rupture of the bonds on either side of the oxygen atom of the three-membered ring, and in each case Walden inversion occurs when an entering anion attaches itself to the carbonium cation in the manner shown below.

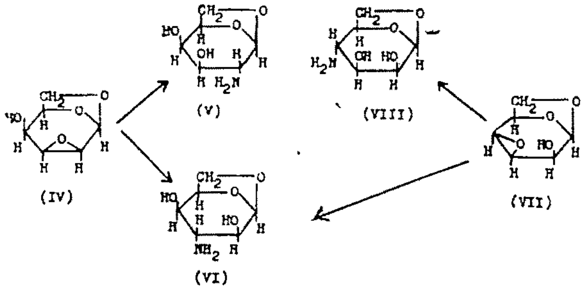


Thus the ring-opening of a derivative of 2 : 3-anhydro-allose with sodium methoxide gives rise to 2-methyl altrose and 3-methyl glucose, and if the ring opening is effected through the agency of ammonia, then the corresponding amino-sugars are obtained. Applying this reaction to a derivative of 2 : 3-anhydro mannose, Haworth, Lake and Peat[2] obtained a 3-amino-altrose (epiglucosamine) derivative and a 2-amino-glucose derivative, the latter being identical with that obtained from natural glucosamine. It was clear, therefore, that with a derivative of 2 : 3-anhydro-talose, ring fission with ammonia should lead to the formation of 3-amino-idose and 2-amino-galactose, which could then be compared with the corresponding derivatives of chondrosamine. Such a derivative of talose, 2 : 3-anhydro-β-methyltaloside (I), was made by one of us[9] and subjected to ring-fission with ammonia. One compound only, namely, 3-amino-β-methylidoside (II), could be isolated in crystalline form, presumably owing to the proportion of the second compound, 2-amino-β-methylgalactoside (III), being small.



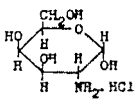
However, 1 : 6-2 : 3-dianhydro-β-talose (IV) (cf. ref. 10), a compound obtained by the alkaline hydrolysis of 2-mesyl-1 : 6-anhydro-β-galactose, appeared to provide more suitable initial material. Its two anhydro-rings have widely different stabilities, the ethylene oxide ring being easily broken by both acid and alkaline reagents, whereas the 1 : 6-anhydro-linkage shows considerable stability towards alkaline reagents but can be broken by acid reagents. Therefore, by treatment of this dianhydride with ammonia, we expected to obtain 1 : 6-anhydro-2-amino-β-galactose (V) and 1 : 6-anhydro-3-amino-β-idose (VI), and by analogy with the investigations on 2 : 3-anhydro-β-methyltaloside, (VI) would be expected to be predominant. There would then remain to be settled the question as to which of the compounds was the idose derivative. This problem could be approached from a consideration of the products obtained by scission of 1 : 6-3 : 4-dianhydro-β-talose[11]

(VII) with ammonia. Theoretically this treatment should give rise to 3-amino-1 : 6-anhydro-β-idose (VI) and 4-amino-1 : 6-anhydro-β-mannose (VIII). Thus the common substance isolated from the ammonolysis of both dianhydro compounds would be 3-amino-1 : 6-anhydro-β-idose. As a natural corollary the second product from the ring opening of 1 : 6-2 : 3-dianhydro β-talose would be the 1 : 6-anhydride of 2-amino-β-galactose (V), and the second product from the ring-scission of 1 : 6-3 : 4-dianhydro-β-talose would be 4-amino-1 : 6-anhydro-β-mannose (VIII).



The practical verification of these predictions has been clearly achieved in the following way: Treatment of 1 : 6-2 : 3-dianhydro-β-talose with ammonia under pressure gave, after subsequent treatment with hydrochloric acid, a crystalline hydrochloride (*A*) in 56 per cent yield together with a residue which, after acetylation, yielded a crystalline triacetyl amino-anhydrohexose (*B*). Similarly, 1 : 6-3 : 4-dianhydro-β-talose gave a crystalline hydrochloride (*C*) in 65 per cent yield, and a triacetyl amino-anhydrohexose which was identical with (*B*) above. The common product (*B*) must therefore be 3-acetamido-2 : 4-diacetyl-1 : 6-anhydro-β-idose, (*A*) must be 2-amino-1 : 6-anhydro-β-galactose hydrochloride and (*C*) must be 4-amino-1:6-anhydro-β-mannose hydrochloride. It is interesting to observe that, whereas in the ammonolysis of 2 : 3-anhydro-β-methyltaloside the idose derivative predominated, in that of 1 : 6-2 : 3-dianhydro-β-talose, the idose derivative was obtained in extremely small amount and was only isolated by virtue of its remarkable readiness to crystallize.

The 2-amino-1 : 6-anhydro-β-galactose hydrochloride was heated with strong hydrochloric acid, that is, under conditions in which the 1 : 6-anhydro-ring opens and no configurational change other than that on C_1 can occur.



(IX)

2-Amino-α-galactose hydrochloride (IX) was obtained in well crystalline form and showed an initial specific rotation of $[\alpha]_D + 125°$ changing to $+ 98°$ in one hour. These figures agree closely with those recorded for chondrosamine hydrochloride. A comparison of the X-ray powder photograph of the synthetic 2-amino-α-galactose hydrochloride and of chondrosamine hydrochloride[7] proved their complete identity. Furthermore, it was possible from (V) to synthesize 2-acetamido-tetra-acetyl-β-galactose, which was identical in all respects with β-penta-acetyl chondrosamine[7].

It is therefore clearly proved that chondrosamine is 2-amino-galactose. Moreover, this synthetic route provides a better means for the preparation of pure chondrosamine hydrochloride than the method of isolation from cartilage.

Full details will be published elsewhere.

IRON AGE FINDS FROM ANGLESEY

NEWSPAPER publicity has already been given to some extremely interesting Iron Age finds recently unearthed in the parish of Llanfihangel-yn-Nhowyn, near the west coast of Anglesey, some five miles to the south-east of Holyhead. The discoveries were made as a result of peat dredging work. It had become necessary to excavate certain bogs in the parish, and one day the attention of the clerk of works was directed to a chain which had been caught up in the teeth of a harrow used for spreading the peat. The chain itself had "come in handy" for dragging bogged lorries on to firm ground! Very wisely it was decided to ask Sir Cyril Fox to visit the site, and as a result of further investigations a large number of very important relics were rescued. Unfortunately, of course, no stratigraphical details could be obtained as excavation by bulldozer or grab does not lend itself to this kind of study; but the amazing fact is that a great many well-preserved objects were recovered which have enabled Sir Cyril to come to certain important conclusions. These appear, together with a detailed study of the finds, in a beautifully illustrated publication by the National Museum of Wales entitled "A Find of the Early Iron Age from Llyn Cerrig Bach, Anglesey" (7*s*. 6*d*.).

The report opens with a more detailed account of the site and the facts leading to the discovery than has been given above. There is also a map. There follows a description of the finds themselves classified under various heads: weapons, horse furniture, objects of social and economic interest, etc., with, in each case, one of those excellent distribution maps of kindred finds which we have learned to expect from the author. Perhaps the most intriguing object is a crescentic plaque of bronze with repoussé ornament. In the centre is a triquetra based on trumpet scrolls with lobed stems and domed mouths, three of which end on one side in a tendril curled round a boss. The whole design is asymmetric. Why this object was so decorated and what it was used for cannot as yet be determined. There follows a general discussion when such problems as dates, cultural affinities, whether the objects are a settlement find or a votive offering hoard, etc., are considered.

The objects can be dated to a period between 150 B.C. and the middle of the first century A.D. Indeed, the upper limit can probably be said to be the destruction of the British culture of the district by the Romans. The finds themselves show clearly that they are not all of local origin, that Anglesey was not a creative centre of art or craftsmanship. This is best seen in a study of the ten bridle bits. It seems clear that Llyn Cerrig was a focal point whither came objects from lowland Britain and from Ireland. This fact reinforces the suggestion that we are dealing with votive offerings—Anglesey, of course, was at this epoch a religious centre—and it would be difficult to postulate there a great market. If the finds do represent a hoard of votive offerings, we may well have to consider that for once we are really concerned with Druid activities, for in Mona who but Druids would supervise such rites at this period ?

Sir Cyril Fox is to be congratulated on having produced a very masterly interim report on these exceptionally important Anglesey finds.

M. C. BURKITT.

FORTHCOMING EVENTS

Tuesday, September 11

QUEKETT MICROSCOPICAL CLUB (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Conversation and the Exhibition of Specimens.

Wednesday, September 12

INSTITUTE OF METALS (at the Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1), at 10 a.m and 2.15 p.m.—Thirty-seventh Annual Autumn Meeting

Friday, September 14

INSTITUTE OF PHYSICS (ELECTRONICS GROUP) (at the Royal Society, Burlington House, Piccadilly, London, W 1), at 5.15 p.m.—Annual General Meeting. Dr. D. S. Evans . "Electronic Conditions in the Sun and Stars".

Saturday, September 15

CONFERENCE ON "FRIEDEL-CRAFTS CATALYSTS AND POLYMERISATION" (in the large Chemistry Theatre, The University, Manchester), at 10.30 a m. and 2 p.m.

Saturday, September 15—Sunday, September 16

ASSOCIATION OF SPECIAL LIBRARIES AND INFORMATION BUREAUX (at Portland Hall, Little Titchfield Street, London, W.C.1).—1945 ASLIB Conference.

Saturday, September 15

At 11.45 a.m.—Prof. J. D. Bernal, F.R.S. : "Information Service as an Essential Factor in the Progress of Science" ; at 2.30 p.m.—Symposium on "Links with the U.S.A.".

Sunday, September 16

At 3.30 p.m.—Discussion on "The Great Book Shortage—its Effect on Education, Research, Empire Intercommunication and the Reestablishment of Cultural Relations in Europe".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned :

ASSISTANT TECHNOLOGIST ENGINEER (with University Degree) for investigation of manufacturing and laboratory processes in connexion with Machinery and Plant Design, London area—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting C.2694.XA (September 14).

RESEARCH ENGINEERS (with University Degree and good workshop training) for development of Industrial Process Plant, London area—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting C.2408.XA (September 14).

AGRICULTURAL CHEMIST—The Acting Director of Agriculture, School of Agriculture, Houghall, Durham (September 15).

LECTURER IN AGRICULTURAL BOTANY—The Principal, Midland Agricultural College, Sutton Bonington, Loughborough (September 15).

LABORATORY ASSISTANT in the Division of Histology—The Bursar, Royal Veterinary College, Camden Town, London, N.W.1 (September 15).

LECTURER (full-time) IN THE DEPARTMENT OF CHEMISTRY—The Principal, Derby Technical College, Normanton Road, Derby (September 20).

CHAIR OF PHILOSOPHY, and the CHAIR OF HISTORY, at the University of Otago, Dunedin—The High Commissioner for New Zealand, 415 Strand, London, W.C.2 (September 21).

ELECTRICAL AND MECHANICAL ENGINEERS (temporary staff) for the Public Works Department of the Nigerian Government, (*a*) Electrical and Mechanical Engineer in charge of Construction, and (*b*) Electrical and Mechanical Engineers—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting D.1420.A (September 21).

MANAGERIAL TECHNICAL EXECUTIVE to a leading firm of manufacturers of Electrical Rotating Machinery in South-east England—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting C.U. 26.XA (September 21).

TOPOGRAPHIC SURVEYOR by Iraq Petroleum Co., Ltd., in the Middle East—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting E.1878.XA (September 21).

LECTURER IN CERAMICS (applicants should be Graduates in Science or Engineering with some knowledge of Chemistry)—The Principal, North Staffordshire Technical College, Stoke-on-Trent (September 22).

TECHNICAL ASSISTANT IN AGRICULTURAL ECONOMICS—The Acting Registrar, The University, Leeds (September 24).

FIRST ASSISTANT PORT ENGINEER by the Government of Iraq for the Basrah Port Directorate—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting E.1895.A (September 26).

LECTURER IN NEURO-SURGERY, and a LECTURER IN NEUROLOGY—The Registrar, The University, Manchester (September 28).

SUB-LIBRARIAN (KEEPER OF PRINTED BOOKS)—The Librarian, The University, Oxford (September 29).

CERAMICS SCIENTIST on scientific staff of Pottery and Ceramics Research Association in New Zealand—The High Commissioner for New Zealand, 415 Strand, London, W.C.2 (September 30).

ASSISTANT IN BOTANY—The Secretary, The University, Aberdeen (October 1).

ASSISTANT LECTURERS (2, Grade III) IN APPLIED MATHEMATICS—The Registrar, The University, Liverpool (October 1).

CHAIR OF CHEMICAL ENGINEERING tenable at the Imperial College of Science and Technology—The Academic Registrar, University of London, Richmond College, Richmond, Surrey (October 8).

SENIOR LECTURER IN CHEMISTRY at the Natal University College, Durban—The Secretary, Universities Bureau of the British Empire, c/o University College, Gower Street, London, W.C.1 (October 15)

LECTURER IN CHEMISTRY (with qualifications in Inorganic and Physical Chemistry) at the Natal University College, Pietermaritzburg—The Secretary, Universities Bureau of the British Empire, c/o University College, Gower Street, London, W.C.1 (October 15).

GENERAL MANAGER of the Croydon Gas Company—The Chairman, Croydon Gas Co., Katharine Street, Croydon (October 15)

ASSISTANT LECTURER IN GEOLOGY—The Registrar, The University, Sheffield (October 31).

ASSISTANT TO THE COUNTY LIGHTING ENGINEER—The County Clerk, Lanarkshire House, 191 Ingram Street, Glasgow, C.1 (November 3).

LECTURER IN VETERINARY SCIENCE, and an ASSISTANT LECTURER IN DAIRY TECHNOLOGY, at Massey Agricultural College (University of New Zealand), Palmerston North, New Zealand—The High Commissioner for New Zealand, 415 Strand, London, W.C.2.

TECHNICIAN (Grade B) IN THE PHYSIOLOGY DEPARTMENT—The Vice-Dean, St. Bartholomew's Hospital Medical College, at Queen's College, Cambridge.

TECHNICAL INDEXER (woman) on the staff of the Plant and Animal Products Department—The Establishment Officer, Imperial Institute, South Kensington, London, S.W.7.

ASSISTANT LECTURER IN CHEMISTRY (must possess an Honours Degree in Chemistry), an ASSISTANT TO THE ADVISORY CHEMIST (must possess experience of analytical work), and an ASSISTANT LECTURER IN DAIRYING (must possess a Degree in Dairying)—The Principal, Midland Agricultural College, Sutton Bonington, Loughborough.

PSYCHOLOGIST (part-time) at the Child Guidance Clinic—The School Medical Officer, Public Health Department, Stour Street, Canterbury.

PSYCHIATRIST (temporary, whole-time) or PSYCHIATRIST or PSYCHIATRISTS (temporary, part-time) in connexion with the Joint Child Guidance Service—The County Medical Officer of Health, County Hall, Lewes, Sussex.

LABORATORY TECHNICIAN (male, Grade B), and a LABORATORY JUNIOR TECHNICIAN (male, Grade C)—The Secretary-Superintendent, Royal Surrey County Hospital, Guildford.

TECHNICAL ASSISTANT TO THE ADVISORY BACTERIOLOGIST, South-Eastern Province, in connexion with the National Milk Testing and Advisory Scheme—The Advisory Dairy Bacteriologist, 39–41 Sackville Road, Hove 3, Sussex

UNIVERSITY DEVELOPMENTS

THE second report on "University Developments" issued by the Association of University Teachers, adopted by the Council of the Association last December, and which appeared in the *Universities Review* of May, has now been issued as a separate document. The report covers as wide a field as the first report, and deals with some questions which have been only briefly discussed in other reports on the expansion of the universities. Three broad subjects are covered : the place of research in the life of a university ; the relations of academic and industrial science ; and the university as a regional focus. The former includes a section on research in the faculty of arts ; but this would appear to be a fragment only of the document quoted and discussed so wisely by Bruce Truscot in "Redbrick and these Vital Days". The section on research in the faculty of science is even briefer, and beyond stressing the need for attention to such points as the improvement of the position of laboratory assistants, as well as in their number, and the place of group- or team-work in research at the universities, contributes little that is new. Criticism of research in the social studies is more searching and constructive ; and in urging that more and more adequate research in the social sciences is of the utmost importance because the progress of man in securing control over his material surroundings has not so far been accompanied by corresponding progress in controlling social and political organization and relationships, and in adapting human beings to their changing circumstances, the report suggests that much research on contemporary social conditions would be done better if initiated and directed by university departments. One reason for this is that it is difficult for an isolated group of persons to obtain access to, or command over, all the distinct disciplines and techniques required in the investigation, analysis and interpretation of complicated and many-sided social phenomena.

Social studies are very unevenly developed in the universities of Britain, and often there is little co-ordination between them. It is desirable that they should be further developed and brought into closer touch within each university and among universities. In her recent book on the training of the social servant, Elizabeth MacAdam referred to the place of the university in training such workers ; she pointed out that investigations into contemporary social conditions which arise out of such courses tend to stress social pathology. More studies of normal societies are needed ; for example, more knowledge of groups within society and of the relation of such groups to one another and to the whole ; of the problems of crowd and group psychology and of leadership ; of the relations of the sexes and the structure of the family ; of the social aspects of education ; and of the trends of change in all these. Moreover, since most social problems involve both facts and values, close relations must be developed between the social sciences and philosophy, and for some problems workers with a philosophical training ;

as well as a knowledge and understanding of social facts will be required. This section of the report accordingly pleads for further encouragement of more thorough research and more co-operation in research, based on historical data, comparative studies of contemporary societies, correlation of different specialisms, and greater co-ordination in planning inquiries. As an example, attention is directed to the economic and psychological as well as biological issues involved in social medicine.

In these separate sections, as in the more general sections on research, the vital importance of research in the life of the university is adequately emphasized and also its intimate relation with the teaching aspect. The two aspects are inseparable and cannot be divorced, and if, as Mr. Truscot points out, caution is necessary in accepting some interpretations of the word 'research' in the arts field, there can be no dissatisfaction with the emphatic defence of the right of full freedom of investigation to be found in this report. Moreover, it is highly satisfactory to find that the Association of University Teachers has not missed the importance to research of such matters as adequate library facilities, the finance of publications, or the interchange of staff which are emphasized so strongly in the report of Dr. Bowman's Committee on Science and the Public Welfare recently published in the United States. An all-round development of library facilities, including books, periodicals, buildings and staff is overdue. Scientific and learned books and periodicals appearing in foreign countries are often poorly represented on university library shelves. The weakness of the scheme for inter-library loans receives pointed comment, and the importance of some portion of the research fund being available to meet the expenses of publication and of greater facilities for exchange of staff between universities and other research institutions is well stressed.

The section of the report on the university as a regional focus deals with large questions which have been ably discussed by Bruce Truscot in both his books as well as in an article in *The Political Quarterly*, and they are also the subject of a lecture by Prof. B. Dobrée delivered at King's College, Newcastle-on-Tyne last year. Here it need only be said that universities will, as the report notes, function as centres of information and ideas for their regions, partly by the independent activities of individual members of university staffs, and partly through the extra-mural departments, the building up of which on a sound and firm basis with adequate recognition from the governing bodies is recommended as a first step. To this end the report suggests the appointment as directors of such departments of persons of academic distinction, with adequate administrative staff; provision of working apparatus and sufficient staff with their own board of study. Scarcely less important is the need for premises, and it is significant that the plan for the development of Manchester at present on exhibition makes liberal provision for exactly the type of accommodation suggested.

Leaving for the present the further comments of the report as to the principal forms of activity and development of the university as a regional focus, we may note that such activities provide a further reason for closer co-operation with other bodies and for some attempt to formulate a national policy for Britain, particularly in view of the post-war developments imminent in adult education. One form of these activities at least is closely related to that major question of the relation of academic and industrial science considered in the second section of this report. The importance of general refresher courses, of short specialist and advanced courses and *ad hoc* conferences among scientific workers and other professional men is now widely recognized. The Association of University Teachers suggests that the provision of such courses may be one of the most important developments of post-war adult education. The universities are the institutions obviously qualified to help in giving the required instruction, and it will demand from them a new approach and much hard work and clear thinking if the best use is to be made of a great opportunity to make an outstanding contribution to the intellectual life of the community. These courses, suggests the report, should be conducted in such a way as to bring about contacts between the various professions and the general public, so that there may be a wider understanding in the community of the basic work of the different professions. They should also help to re-establish touch between the universities and many of their alumni; and their financing, which will not be easy, should be done in co-operation with the professional bodies concerned.

It is to such co-operation between the universities and the professional bodies that we must also look, as the Nuffield College statement on problems of scientific and industrial research suggested last year, for the solution of some of the more difficult problems arising in the relations of academic and industrial science. That the Association's report should be concerned with these problems is the more welcome in view of the attention they have received in the United States by the able committee under Dr. Josiah Bowman as chairman, to which Dr. Vannebar Bush referred the consideration of questions relating to science and public welfare in preparing his report on a programme for post-war scientific research. The parallel in thought between the two reports is striking, and no one could wish for a more emphatic endorsement of the importance of the fundamental freedom of inquiry.

The universities, points out the Association of University Teachers, are the main sources of that fundamental research which, through subsequent development in the field of applied science, is one of the chief determinants of progress in a modern community; they are also the most effective institutions for ensuring that applied science is kept in full touch with expanding scientific knowledge. The Association claims that the highest standards of mental development and training in clear and critical thinking to which the university aspires to lead its students can be achieved through the teaching of technological subjects, as well as of the humanities or pure science, and urges that the development of the existing applied science departments is to be encouraged and new sections should be formed when sub-divisions have sufficiently increased in content and significance. In particular, the newer practical developments of biology should find full support in the expansion of teaching and of research; and special reference is made to the importance of genetics, ecology, and soil science.

Such developments represent one direction in which some measure of joint planning between the universities is desirable; and, again, in the establishment of new institutes for the application of fundamental research to the needs of industry, full consideration should be given to the arguments in favour of placing them near a university in the region most engaged in the industry concerned. Such institutions should maintain the closest touch with neighbouring laboratories engaged in fundamental research, and proper attention to this point should do much to close the gap between fundamental and applied science. The Joint Standing Council set up in Manchester last year by the University and the Chamber of Commerce is an example of the way in which such co-operation can be fostered.

The universities, however, must be the sole arbiters of the type of work which they shall undertake. There must be no suggestion that they should be in any way under the direction of the research institutes in this respect; and this freedom of fundamental research in the universities from external control is again stressed in connexion with the departments of applied science. In particular, the Association urges that the growing tendency of industries and individual firms to subsidize *ad hoc* research in universities on their own particular problems is in general to be resisted, as liable to lead to a form of commercial domination which is alien to the true university spirit and to the advancement of science itself. Effective contact with the industrial world can be maintained in other ways, and it is very desirable that assistance from non-industrial sources should be sufficient to ensure the independence of university research, especially on the technological side. In so far as applied research is carried out in university laboratories, the results should be immediately available to industry as a whole.

It is of course true that industrial research often discloses gaps in our more fundamental knowledge, and in this way industry may be able to indicate to the academic scientific worker problems which are worth investigation. Contacts between industry and the university such as are fostered by joint research councils of the type established at Manchester should encourage this cross-fertilization of ideas; and for this reason again the somewhat different problem of the engagement of professors or lecturers as consultants to firms or research associations requires careful handling. In principle, the intellectual resources of a university should be available to all in the community, and no restriction should be placed on the giving of advice by members of the academic staff, apart from the normal clause forbidding the acceptance of outside appointments without the consent of the university. So far as payment is concerned, the Association of University Teachers looks to the evolution of a code of professional conduct in such matters, as was suggested in the Nuffield College statement.

It will be seen, therefore, that the Association has covered the ground very thoroughly. Such questions as the relations between the universities and the technical colleges are also tentatively considered, and the importance of developing further links between them is recognized—for example, in addition to closer regional association, the setting up of joint standing committees by subjects, as well as between governing bodies, to investigate possibilities of mutual aid in the difficult post-war period is suggested. But what is most significant, however, is the extent to which the views urged by the Association find expression in the reports which have since appeared from Dr. Bowman's committee in the United States, already mentioned, and from the Commission on Higher Education in the Colonies. It would, in fact, be difficult to find a better brief exposition of the place of research in the life of the university than is contained in Chapter 6 of the latter report, and of the implications which arose from the acceptance of this conception of the place which the search for knowledge should hold in a university.

A university is not a continuation school in which the staff have time for research; it is an organ of higher learning inspired throughout by devotion to knowledge, and for the teaching staff the obligation to further knowledge in their special fields includes the duties of keeping constantly in touch with the results of research and of preserving a continual readiness to consider new ideas and to make the adjustments of outlook that follow from the acceptance of new data. For those who control universities, it means that the knowledge sought is desired for its own intrinsic value; the motive proper to a research worker is to extend the boundaries of charted knowledge in his own field wherever extension is intellectually most satisfying. Accordingly, utilitarian results must not be demanded from the research activities of members of the staff of a university, and their work must not be judged by its immediate bearing upon practical problems.

If these first principles are fully apprehended, and if those in control realize that in the long run universities will be judged by the contributions which they make to fundamental knowledge, there is little need to fear that some of the dangers to which Bruce Truscot and the Association of University Teachers direct attention will not be averted. It is not only in the Colonial universities that the choice of subjects for research is constrained by circumstances which make some desirable projects difficult or impossible to attempt, or that in the post-war world the necessary adjustment to new problems and new conditions may in itself provide a welcome and valuable stimulus. Again, in regard to the applied sciences, it is not the function of the universities directly to provide for the urgent application of science to improve health, agriculture or industry in the Colonies; to require the universities to do so would indicate a fundamental misapprehension of the place of research in universities. It is, on the other hand, an important duty of the university to train students to become applied scientists, and the abundance and attractiveness of local material, in the Colonies, as elsewhere, will not infrequently lead the university research worker, though untrammelled by the need to produce utilitarian results, to devote himself to inquiries which will have considerable practical significance. Equally, fidelity to such principles will be the surest guide in resolving the problems of relations and location between the institutes of applied science and the universities in the colonies as in Great Britain.

The Bowman Committee, in laying down similar general principles for the endowment of research in universities in the United States, has been influenced by the growing reliance of science departments of American universities upon industrial corporations for assistance. This, and the accompanying tendency to specify the projects for which grants to universities or to research institutions are to be used, have already been the subject of pointed comment. The Bowman Committee emphasizes the need for freedom in science, and refers to the need for guarding against the control of science by industry as well as against control of science by government. It points out, further, that reliance on industry in this manner may imply the distortion of university research in the direction of short-range problems at the expense of more fundamental research, as well as some decrease in the freedom of the university man of science.

The insistence in the Bowman Report on the necessity of devising ways and means of allocating funds in large measure without determining what particular problems are to be worked on and who is to execute them, and the importance of variety and decentralization of control in scientific work, where the fostering of novelty must be the first concern, is one way in which thought in the United States is clearly moving on similar lines to that in Great Britain. That in itself should help to overcome the complacency of which Bruce Truscot complains ; and it may well be that the increased contacts in certain fields during the War will have facilitated the further pooling of experience in dealing with some of these problems, and especially with the removal of those war-time obstacles which have hindered the free exchange both of information and ideas and scientific workers. The general desire of scientific men in Britain, the United States and the U.S.S.R. for more such contacts and for full freedom of communication is unmistakable ; but in the meantime this further report on university developments from the Association of University Teachers merits close study by all research workers. It is well to note that the Association, in consultation with the University members of Parliament, has drawn up a memorandum in which the more important needs of the universities are set forth in order of priority ; that memorandum, published in the *Universities Review* last May, also deserves attention by all concerned with education or research. The release of university staff and of students in Britain to complete their studies has received nothing like the priority that its importance for the new educational programme, the expansion of our research effort or industrial development demands.

PSYCHOLOGY OF WAR

Foundations of Human Conflicts

A Study in Group Psychology. By Dr. William A. Brend. Pp. viii+212. (London: Chapman and Hall, Ltd., 1944.) 15*s*. net.

THE psychology of conflict in human affairs, rising to an extreme of violence and cruelty in war between nations, is a subject of study second to no other at the present time. Although the great majority of educated and thinking people imagine that they can solve this problem in general terms by the light of common-sense and on the basis of ordinary experience, the mutually conflicting theories which they put forward indicate that no adequate solution can be reached in this way.

Dr. Brend's book may be regarded as the latest illustration of such a position. Although written by a sound physician with a legally trained mind and with a good working knowledge of medical psychology, it approaches the problem of human conflict along the lines of descriptive psychology, in which it is conscientiously precise and accurate, without probing more deeply into the fundamental springs of human activity.

Dr. Brend draws an important distinction between 'direct' and 'derived' emotions, and endeavours to explain the development of strife between groups, whether national or religious, between classes or ages, in terms of an artificial stimulation of derived emotions among the masses by the use of myths and symbols, by falsified history and irrelevant or outworn tradition, applied along the lines of the most up-to-date propaganda. He denies the existence of any instinct of pugnacity, or of the herd, or of religion, but considers that all these reactions are acquired by the individual after birth, under the influence of derived emotions which are, to say the least, inadequately controlled by reason and direct experience.

His ultimate solution would seem to be an extreme application of *rationalism* to the problem, whereby differences of nationality, of religion and of classes should be ultimately abolished. Nevertheless he shows little realization of the close and intimate relationship of the emotional and rational elements in the human soul, nor of the great importance of the 'spirited element' (τὸ θυμοειδὲς μέρος) as Plato saw it.

In spite of Dr. Brend's denial, there can be little doubt of the instinctive basis of pugnacity, gregariousness and the *general* religious attitude and outlook in man. There is an inborn tendency at the root of each of these mental reactions which is intimately related to a general instinct of self-preservation (*Selbsterhaltungstrieb*), even if we refrain from positing a more active tendency to aggression and to worship independently of individual experience. *Sublimation*, after release of repressions, is the only healthy result to be aimed at, and the only satisfactory solution of the problem of innate pugnacity.

Man is a fighting animal, and will at least defend himself when he is attacked. He will refuse to take unfavourable economic conditions lying down, and will combine and fight, both for his class and for his nation, when conditions become intolerable. In other words, he will fight to defend himself against objective enemies and difficulties.

But in his own individual development, onwards from infancy, he has had to contend with difficulties that were often too much for him, so that he has accumulated grievances and grudges, and, in general, *hates*, which continue to plague him from within, and their cumulative subconscious effect is to make him envious, spiteful and jealous, and unduly *suspicious* of his fellows, or some of them. He becomes on the defensive subjectively, and projects his stored-up hate and aggressiveness upon the people around him, considering them his enemies and putting himself on guard against them. In other words, he becomes *paranoid* in his mental attitude towards his environment.

As a member of a group, especially of a nation, with its sensitive national pride, his paranoid tendency is shared by his companions in relation to the common foe, and in their company he is ready to play his part in fighting the hostile nation by whatever means are available, sustained in his pugnacity by propaganda and by a consciousness of the rightness of his cause.

Once battle is joined, as in a dog-fight, he will not desist until he has destroyed the enemy or the enemy has destroyed him. The time to stop a war is before it starts. If nations were fully informed by their leaders of the facts of the international situation an outbreak of war might be delayed, but it would not necessarily be prevented. Nations and their leaders may be self-deceived at a deeper psychological level, and it is here that the psychological roots of war are to be found—in addition to the more obvious economic causes.

In other words, only by deep mental analysis—along the lines of Freud's method of psycho-analysis, but without prejudice as to the special sexual theory which he and his followers have developed in their study of both normal and psychopathological cases—can the full psychological meaning and causation of human conflicts, both individual and group, be revealed. Many investigators are now at work along these lines, and they have incomparable material in the latest war with Germany, if they know German and are prepared to make a *direct* study of the minds of Germans as well as those of their own countrymen, not omitting *themselves*. The end is self-knowledge, free from illusion or self-righteousness.

WILLIAM BROWN.

HUMAN EMBRYOLOGY

Human Embryology

(Prenatal Development of Form and Function). By Prof. W. J. Hamilton, Prof. J. D. Boyd and Prof. H. W. Mossman. Pp. viii+366. (Cambridge: W. Heffer and Sons, Ltd., 1945.) 31*s*. 6*d*. net.

ADVANCES in the field of human embryology during the present century have been dependent chiefly upon the acquisition of more abundant human material, particularly in the earlier stages of development, and upon its accurate observation and interpretation in the light of comparative and, to a lesser degree, experimental embryology. Undoubtedly the most notable recent advances have been in the study of early human and primate material, which is now becoming available in steadily increasing quantities. In this new text-book, the authors have attempted "a presentation of the subject of human embryology in the light of the advances which have been made in it during the past twenty years". They have, in general, succeeded in working into existing knowledge many facts which have been collected during the past twenty years.

The text follows the customary order, dealing in turn with the germ cells, accessory sexual organs, fertilization, implantation, early developmental stages, including the fœtal membranes and organogeny. Chapters are also included on some elementary and fundamental concepts of experimental embryology and on comparative embryology. Each chapter is provided with a list of references which are described as 'full'. It is regrettable that no mention has been made of the life-work of three great English anatomists, namely, Elliot Smith on the nervous system, Fawcett on the skull and Wood Jones on the urogenital system. There are detailed references to that great American publication "Contributions to Embryology", and its influence is much in evidence throughout the book both in the text and figures.

The illustrations are numerous, many being in colour. Original figures are in a minority, and do not attain the high standard of accuracy found in most of the copied or modified figures. It is a pity that there are inaccuracies in these figures, as in a text-book for students accuracy should come before all else. To mention some, in Fig. 136 the vertebral artery is labelled as a precostal anastomosis; Fig. 150 is that of a sagittal section of a fœtal head and conveys an entirely false impression as to the form and dimensions of the nasal cavity at this stage. In another figure the chorda tympani is shown passing above the first pharyngeal pouch. The vitelline artery and vein are shown in Fig. 176 passing to their destination outside the mesentery of the small gut, while the relations of the Wolffian duct to the ureter differ in Figs. 207 and 212. Indeed, the error in Fig. 207 would make the transformation which is shown in the succeeding figures impossible to understand. The changing relations of the suspensory ligament of the gonad to the metanephros shown in figures dealing with the urogenital system can do little but confuse the observant reader. In Fig. 330, based on Macklin's diagrams, the tympanic bone is indicated as a cartilage bone, while in the succeeding figure it is correctly depicted as a membrane bone. Correlation between the figures and the text is in many places unsatisfactory. Structures such as the paracondyloid process, ala hypochiasmata, alicochlear commissure and polar cartilages are figured and labelled but receive no mention in the text and fail to appear in the index.

The account of early human developmental stages is excellent and constitutes one of the most valuable features of the book. Many details of known early human embryos are tabulated and recorded. This is a field in which at least one of the authors can speak with considerable authority and gives a valuable summary of the formation of the germ layers and implantation as it is now known. The sections on the lymphatic system and on teeth could with great advantage be enlarged and elaborated. The development of the heart is clear and well written; but it is a little surprising to note the omission of the term infundibulum of the right ventricle both in the text and index. Speaking of this part, Keith said, "The importance of recognizing the bulbus cordis as a separate constituent of the heart will be realized when it is remembered that 95% of the cases of congenital malformation are the result of its imperfect transformation to form the infundibulum of the right ventricle of the heart". It would appear that it is impossible to lay too much stress on this part.

Congenital abnormalities and disease are considered briefly, while the possible mechanisms of malformation, twinning and monstrosities are discussed.

The choice of epiloia as an example of a purely ectodermal disease is misleading, both on account of its rarity and of the mesodermal tumours in the dermis, heart and kidney which seem to co-exist in a great majority of the cases.

Most text-books of human embryology suffer from one serious defect, namely, the inadequate picture which is conveyed of that most interesting of all newborns, the human babe at birth. This book is no exception. Ballantyne's account in that infrequently read book "Antenatal Pathology and Hygiene" still remains one of the best and most concise. Embryology should not only help the student to understand adult anatomy but also neonatal anatomy and physiology, upon which so much depends. The fact that the fœtal and newborn kidney is lobulated is not mentioned in the text of this book, though it is frequently so depicted in the figures, while the term fontanelle does not appear within its covers.

The book is beautifully produced. Typographical errors are few and the photographs and figures are well reproduced. It is a credit to the publishers that they find themselves able to offer such a profusely illustrated volume at so reasonable a price. The student will undoubtedly appreciate the excellency of the production, as well as the concise presentation of the many and important aspects of human embryology now made available to him.

D. V. Davies.

FRANÇOIS MAGENDIE (1783–1855)

François Magendie

Pioneer in Experimental Physiology and Scientific Medicine in Nineteenth Century France. By J. M. D. Olmsted. Pp. xvi+290+1 plate. (New York: Schuman's, 1944.) 5 dollars.

PROF. J. M. D. OLMSTED has followed up his excellent life of Claude Bernard with one of François Magendie, Bernard's teacher and one of the great figures in the rise of scientific medicine. Trained in Paris during the period of the Napoleonic Wars, Magendie worked in a period when medicine began to discard the traditions of the eighteenth century and to depend on more critical and exact observation and experiment. Bichat, Laennec and Corvisart were his seniors, and Flourens and Le Gallois his contemporaries. French medicine was in the ascendant, and Magendie, professor at the Collège de France from 1831, contributed to its development by his work in physiology and pharmacology and by his uncompromising criticism.

Magendie was before all things an experimental physiologist, and his name survives in the 'Bell-Magendie law' of conduction in the spinal roots and in the 'foramen of Magendie', the opening through which the cerebro-spinal fluid passes from the interior to the exterior of the brain. Probably the Bell-Magendie law is rightly named, for Charles Bell, the brilliant Scottish anatomist, and François Magendie both had a hand in its discovery; but Magendie always felt that the main credit was his and did not hesitate to say so. Prof. Olmsted's critical account of the long controversy shows that he had some reason for his claim, since his were the decisive experiments. But his contemporaries favoured Bell, and Magendie's quarrelsome habits may have made them glad to do so.

In medicine Magendie remained the experimental physiologist. With his lack of respect for tradition, he found much to overthrow though he had little to put in its place. He had no use for copious bleeding and purging, the established treatment of the time, though his internes were so distressed at this neglect of his patients that they sometimes bled them without his knowledge. His studies of the effects of drugs on animals (the beginnings of experimental pharmacology) did not encourage him to use more than a few well-tried medicines, and he was often content to leave the disease to run its course. Flourens wrote of him: "To young doctors he was fond of saying 'You have not tried doing nothing yet. . . . More often than not we cannot discover the cause of a disease. Our only function is to assist Nature, which always tries to restore the normal state, by refusing to hinder her; we can hope only sometimes to be skilful enough to aid her'." But his patients relied on him none the less, and he was far kinder to them than to most of his scientific colleagues.

Nor did Magendie neglect to look for the causes of disease. He made a special journey to Sunderland in 1831 to report on the outbreak of cholera there. He was appalled at the wretchedness, filth and poverty of the houses, but argued that the disease was not contagious. His views on contagion seem, in fact, to have been based on the belief that a disease could not be contagious if he himself had been exposed to it and had not been infected. He had certainly exposed himself, in Sunderland and afterwards in the Paris epidemic of 1832, where he worked day and night at the Hotel Dieu with a small band of internes and nurses.

Magendie's views were certainly wrong sometimes, and he would not admit that they were until he had seen the experiment which disproved them. He was intolerant, resented criticism, made enemies and was regarded by many as a monster of cruelty for his vivisection of animals. But he was fearless and honest, and medical science owes a great deal to his deliberately sceptical attitude, forcibly maintained and upheld by his great authority as a physiologist. Prof. Olmsted's biography is careful, well-balanced and interesting. It is to be hoped that he will write more of this period which he knows so well.

E. D. Adrian.

HAY-FEVER PLANTS

Hay-fever Plants

Their Appearance, Distribution, Time of Flowering and their Role in Hay-fever, with special reference to North America. (Plant Science Book, Vol. 15.) By Roger P. Wodehouse. Pp. xxvi+245. (Waltham, Mass.: Chronica Botanica Co.; London: Wm. Dawson and Sons, Ltd., 1945.) 4.75 dollars.

FOR a plant to be an important cause of hay-fever it must shed its pollen freely, must produce large amounts of pollen, must grow in great abundance, and must have active allergens in the pollen grains. Most wind-pollinated plants satisfy the first condition, but anemophily and entomophily offer little guide to the second. Relative abundance is of immense importance as a distinguishing factor between species of great and small importance in hay-fever; thus only about thirty-five species of grasses out of the thousand or so in the North American flora are important hay-fever plants. Lastly, the allergic qualities of species also differ widely, appearing with fair constancy in the following families : Gramineæ, Compositæ, Chenopodiaceæ, Amaranthaceæ, Plantaginaceæ, Polygonaceæ, Betulaceæ, Fagaceæ, Ulmaceæ, Moraceæ, Juglandaceæ, Salicaceæ, Aceraceæ and Oleaceæ.

If to these considerations we add the differential susceptibilities of patients to various types of air-borne pollen, the immense variation in local occurrence of the species concerned, and their various times of flowering, it will be apparent how large and complex a field of botanical inquiry lies behind the scientific study of the causes of hay-fever. Such study has of recent years made great progress in the United States, and one of the foremost research workers on pollen characterization and identification, Dr. R. P. Wodehouse, has now published a useful and timely summary of present knowledge of hay-fever conditions in that country.

An introductory chapter explains the origin of air-borne pollen and describes the chief methods now employed in estimating the pollen content of the air, filtration, the air-centrifuge, and gravitational settling, combined with microscopic identification. It is interesting to have the first tentative estimates of the minimal pollen doses which will produce hay-fever symptoms. For the ragweed (*Ambrosia* spp.) this appears to correspond with a pollen frequency of about 200 grains per cubic yard of air, or a daily inhalation of about 4,000 grains.

Subsequent chapters give brief descriptions of all the species now recognized as concerned, or possibly concerned, with hay-fever in the United States, with accounts of form, habitat and flowering season, illustrations of the plants, and full description and illustration of the pollen grains.

Lastly there follows a valuable analysis of all the recorded data for the United States treated on a basis of twelve geographical regions, for each of which there is given a comprehensive chart illustrating the frequency and flowering season of all the hay-fever plants. From this information both clinician and botanist will derive much help. We can see at a glance how in the north-eastern States there are three phases of hay-fever in the year—the unimportant early spring phase of tree pollen, the important early summer grass pollen phase, and the very important late summer ragweed pollen phase. This contrasts strongly with conditions in the southern States, where the long growing season gives many continuous months of hay-fever conditions to which many pollen types contribute. In this section we find also discussed how the weediness of undeveloped building estates makes for bad hay-fever conditions, and how forest cover and maritime situation offer good conditions suitable for hay-fever resorts.

It is very striking to the English botanist to observe that most of the grasses which are serious causes of hay-fever in the United States are those introduced from Europe, such as *Anthoxanthum odoratum*, *Poa pratensis*, *Phleum pratense*, *Agrostis alba* and *Dactylis glomerata*, while with them is associated *Plantago lanceolata*. Presumably the reason for this is that these are all weeds or cultivated grasses now abundant around the big population centres which are comparatively out of reach of pollen borne by the wind from the prairies. Otherwise one would not expect the native prairie grasses to be so overweighted in effect.

It is to be hoped that this book will encourage much similar work, not only in the United States, but also in Great Britain, where hitherto only Hyde and Williams have made significant headway in this direction.

H. GODWIN.

METHODS IN CLIMATOLOGY

Methods in Climatology

By Victor Conrad. Pp. xx+228. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1944.) 22*s*. 6*d*. net.

In this book, Dr. Victor Conrad, formerly head of the Austrian Meteorological Service, and now research associate in climatology in Harvard University, gives an outline of methods of treatment of observations, as distinguished from results of the treatment.

The book is in four parts, the first dealing with the general methods of statistical discussion, including the evaluation of frequency distributions, the mean, median, mode, etc., the fitting of curves to numerical data, the smoothing of data, and the essential formulæ of harmonic analysis.

The second part deals with the representation of characteristic features of different elements. Thus under the heading of temperature we find the discussion of the relation of the mean of two or three observations made at standard times to the 'true mean', which is the mean of 24-hourly observations, and the evaluation of spells of weather which satisfy certain conditions. Rather similar technique is applied later to rainfall measurements. The methods of evaluating resultant wind velocity from records of the velocity and direction, and the resultant wind direction from the frequencies of the directions alone, are discussed in a separate chapter. All these topics are relatively simple and could perhaps have been treated more briefly.

While there are frequent references to original papers, the author now and again fails to explain an important point. For example, on p. 111 he gives formulæ for the evaluation of the drying power of the air, the effect of the wind speed, v, being represented by a factor $F(v)$. A table of values of $F(v)$ is given for a wide range of values of v, presumably from a paper by Knoche. The reader would have profited from a hint as to the form of the function $F(v)$, particularly in view of the fact that a few pages later, in discussing cooling power of the air over a wet surface, the author gives a very different function of v in his equations.

The third part of the book deals with methods of spatial comparison. Methods of testing relative homogeneity of observations, and of the reduction of climatological averages to a uniform period, are briefly treated. Formulæ for computation of the coefficient of correlation, and of the regression coefficients, are given later. Here the reviewer felt that emphasis should have been laid on the practical forms for computation, which are $r=\Sigma xy/\{\Sigma x^2.\Sigma y^2\}^{\frac{1}{2}}$ and $b=\Sigma xy/\Sigma x^2$ respectively, and not $r=\Sigma xy/n\sigma_x\sigma_y$ and $b = r\sigma_y/\sigma_x$. The methods of anomalies, the use of wind roses and stream-lines are briefly discussed.

The fourth part deals with climatography, or the presentation of a complete picture of the climate of a region. This part is of interest in that it brings into prominence a number of features of climate which are frequently overlooked; but it does not sufficiently emphasize the fact that a satisfying description of a climate should deal, not only with the monthly means over a period, but also with the variability from the mean.

This book, which is in general simple in its treatment of the questions discussed, will be a help to many a beginner in the subject.

Post-War Educational Reconstruction in the United Nations

21st Educational Year Book of International Institute of Teachers College, Columbia University. Edited by I. L. Kandel. Pp. ix+341. (New York: Bureau of Publications, Teachers College, Columbia University, New York City, 1944.) 3.70 dollars.

THIS book is of special interest at the present time, when attention is being directed to the future of education, and to the prospects of a new start, based upon the ideals for which the War has been, and still is being, fought. The havoc wrought by the aggressors on educational systems in the occupied countries is here described; the problems that confront each of the countries are discussed; and the programme for reconstruction in the years following the final victory of the United Nations is presented. The book contains articles on Australia, Belgium, Canada, China, Czechoslovakia, England, France, Greece, Italy, the Netherlands, New Zealand, Norway, Poland, Scotland, the Union of South Africa and the United States. The omission of an article on Soviet Russia is due to circumstances over which the editor had no control; and the absence of an article on Yugoslavia reflects the uncertain political situation in that country when plans for this volume were being made.

This is the twenty-first volume of the Educational Yearbook of the International Institute of Teachers College, Columbia University. During the whole period the Yearbook has been edited by Prof. I. L. Kandel, who now has to make the melancholy announcement that this volume will be the last in the series. The news will be received with great regret by students of education in many lands who have derived both pleasure and profit from the Yearbook. The editor places on record his indebtedness to the Rockefeller Foundation and the Carnegie Corporation of New York, which made publication possible, to the willing co-operation of contributors, and to his able secretary, Miss Gilroy. To all these must be added Prof. Kandel himself, the moving spirit of the whole enterprise.

The Blackbird

A Contribution to the Study of a Single Avian Species. By A. F. C. Hillstead. Pp. 104+19 plates. (London: Faber and Faber, Ltd., 1945.) 8*s*. 6*d*. net.

IT is wrong, to my mind, to tell a child not to be cruel to animals; it puts the very idea of cruelty into his mind, and the living creatures remain animals, or even beasts, for him. He had better grow up among the mouse-people and the sparrow-people and the pussy-cat-people, and all the other friendly people who share the world with each other and with him. This is the wholesome spirit in which Mr. A. F. C. Hillstead writes about the blackbird, in the company of which he has lived for years, until he knows him body and soul. There is not a thing in his little life which Mr. Hillstead has not studied and described: his song, his 'territory' or law of landed property, his courtship and nest-building and care of his young, his migrations on holiday jaunts, his general intelligence, and all the diverse occupations of his livelong day. Mr. Hillstead has much to tell under all these heads, and more besides. The blackbird is no world-wanderer, like stork or swallow, but he does love a change of air; he likes to 'go places', like civilized man. He comes across the Channel to share our milder, insular winter; he is partial to Ireland; he cares little for Devon, and openly dislikes Cornwall, strange to say. His song is described with full sympathy and comprehension; "by and large, it has no equal; there is nothing to touch the rich flute-like tones which are so essentially British".

The whole story is illustrated with photographs by bird-loving friends. These are wonderfully beautiful; they show all sorts of situations of the nest, and all sorts of occupations of the bird. In short, we have here, to the life, our old friend "so black of hue, with orange-tawny bill"; and his wife and children, and his house and home, and everything which is his. D'ARCY W. THOMPSON.

Sun Compass

By Francis Chichester. Pp. 10+Compass. (London: George Allen and Unwin, Ltd., 1944.) 5*s*. net.

THE sun compass is designed for use anywhere in a belt round the world within two hundred miles north and south of a line from Birmingham to Berlin. Knowing the date and the local time, a simple setting of the sun compass enables one to take the sun's bearings to an accuracy of about 2°, and with practice an accuracy of 1° is possible. A rotating disk has the months marked with dates which vary from six to twenty days. Thus September 16–22 is included in one date, June 1–21 in another, and so on, and a 'model sun' for each of these periods is marked on the disk. On a transparent graticule are marked the hours from 4 to 20 and also curves showing the sun's bearings from 50° to 300°. The bearings are given for every 10°; but it is easy to interpolate to an accuracy of about 1°.

On the back of the card there is a compass rose by which bearings other than those of the sun can be obtained. This involves nothing more formidable than setting up a pencil on a degree circle, so that the shadow of the sun falls on the centre of the compass rose, which is then rotated until the shadow cuts the degree scale at the desired division. The maximum error that can occur at places 3° north or south of the Birmingham-Berlin line is 3°, but this takes place only at midsummer and even then only at certain times in the day. It seems possible that there may be a demand for this very convenient instrument (it measures 5½ in. by 5 in.) for other latitudes. Having checked some of the results, using rigorous formulæ and four-figure tables, it is surprising to find the high degree of accuracy obtained over the range of latitudes. M. D.

The Science of Nutrition

By Prof. Henry C. Sherman. Pp. xi+253. (London: Oxford University Press, 1944.) 15*s*. net.

THIS is a book about nutrition for the layman. Prof. Sherman describes the three main functions of food as first, provision of energy; secondly, supply of structural material for the growth and maintenance of tissue; and thirdly, the provision of substances which maintain the body's self-regulatory system and physico-chemical balance in tissue.

On this basis is built an excellent survey of the recent developments in the science of nutrition in its personal and economic aspects and applications. Purely scientific terms and descriptions are kept to a minimum, but a selected bibliography is provided for those readers whose interests go beyond mere broad information. The wide scope of this work is indicated by the inclusion of a summary of work on 'tagged' atoms in the study of metabolism.

RADAR IN WAR AND IN PEACE

By Sir ROBERT WATSON-WATT, C.B., F.R.S.

It is customary, but not invariably wise, to preface an account of a new subject with some attempt at a definition. There being no part of the problem more difficult than accurate and condensed definition, this custom makes the whole subject look more difficult than it really is. For this reason the immediately following section of these notes on radar might well be annotated, as in some prescribed text-books, with the remark "May be omitted at a first reading".

On Defining 'Radar'

To devise, and to interpret, an adequate definition of 'Radar' would be more laborious than profitable. The group of varied and flexible but intimately related techniques which have grown from a common stem of R.D.F. or radiolocation in Great Britain and radar in the U.S.A. have it in common that they involve essentially a measurement of distance, inferred from a relative time-delay and an assumed or known speed of travel of radio waves. But they have much more in common, and they are far from being merely radio range-finding systems. They might not have been achieved without Appleton's classical range measurement on the ionosphere; they would not have been practically useful without Breit and Tuve's powerful tool of the radio pulse, which carried Fizeau's method out of the optical laboratory into the upper air.

At the least, a radar system must provide an unambiguously associated pair from the three co-ordinates required to specify the position in space of the material object to be located by radio means, and must present these co-ordinates in a form convenient to the user. It should and normally does measure the third co-ordinate (usually stated as flying-height) in the case of aircraft, and it frequently gives additional information about identity, numbers, speed in line of sight, and so on.

It would be pedantic, unrealistic and unhelpful to restrict 'radar' to the "location of an object without active co-operation from that object". The radiolocation of friends will, happily, be a far more general practice than the search for enemies, and active co-operation from the friend should not be ruled out as 'not cricket'. Nor should the emphasis be on 'an' object. The very essence of radiolocation, alike for war and for peace, is that it began with a determination to achieve something more practical than one of several possible systems which could locate 'an' aircraft alone in space, or could continue to locate an aircraft once an initial position was known, to the neglect of all the other aircraft in the sky and of the initial pick-up problems.

It would be artificial and misleading to confine the adjective 'radar' to systems involving the reflexion of radio energy from the object to be located, or even to the return of energy from the object towards the primary radiator. The most generally installed radar equipment of all was the 'Gee' receiver, which enabled the air navigator to determine his position by measuring the relative times of arrival of radio pulses emitted synchronously from three ground stations. The techniques involved in this 'one-way traffic' system of pulses, travelling from ground to aircraft or from shore to ship but not back, are quite inseparable from the techniques used in the 'H' and 'Oboe' systems, in which the primary radio pulses 'interrogating' the mobile craft automatically release from it a series of reinforced, coded, and conveniently frequency-displaced reply pulses, which travel back towards the primary radiator. And the techniques of all these, and of the I.F.F. system from which 'H', 'Oboe' and radar beacons grew, are in turn quite inseparable in general conception and broad execution from those which are used to extract somewhat lower accuracies at somewhat shorter ranges from the somewhat less informative radio echoes returned from a non-co-operative aircraft.

So in practical life radar is a group of techniques which enable the position of one object among many to be measured by radio means, involving essentially the measurement of relative time-delays and thence the total paths or difference of paths, in the travel of suitably labelled radio waves between the object to be located and the radio station or stations (which may be transmitting, receiving or receiving-and-retransmitting stations) which provide reference points for the location. The 'labels' attached to the radio waves may be a controlled change of frequency, as in the Appleton foundation experiment in radio range-finding, or a controlled change in amplitude, of which Breit and Tuve's pulse technique is the almost universal application.

The Pulse Technique

The pulse technique has attained this universality because it satisfies a number of special needs simultaneously. The beginning or 'leading edge' of the pulse marks a packet of energy which can be re-identified after the vicissitudes of travel, thus permitting accurate measurement of time of travel, and the end or 'trailing edge' marks the beginning of an invaluable clear period in which the radar echoes or response signals can be received free from the overlaying and interfering effect of the primary signal. In modern pulse technique, pulses which may be very brief indeed are sent out at a very accurately controlled recurrence frequency, and displayed on the equally accurately synchronized time-base of a cathode-ray oscillograph. This gives a cumulative preference to the slowly changing pulse-responses over the random noises occurring along with them, since the successive responses are more or less accurately superposed while the noise is spread more or less evenly over the background. The interval between primary pulses is preferably made just greater than the time-delay of the response from the greatest distance to be sounded. The time base then becomes a range-scale, with its zero at the leading edge of the primary pulses, and it can be made linear in time and range. Care must, however, be taken that echoes or responses received after a time-delay greater than that between primary pulses are not read as coming from a distance less by one or more whole pulse-periods than their true path. Finally there is a considerable advantage in discrimination to be attained by using the pulse-recurrency frequency as a coding characteristic of the stations concerned, and by additional coding by pulse-width or multiple pulse-spacing, or both. These advantages of the pulse system are bought at that price in increased width of frequency channel occupied which is the inescapable price of high information-carrying capacity.

The superposed successive pulses returned from any one reflecting or responding object can be treated as a continuing signal coming from that object, unmixed with others of different time-delay, and can thus be subjected to standard processes of direction-finding, in azimuth and elevation, independently of the corresponding series of responses from more or less adjacent objects. And if the responses come from closely spaced objects, such as a tight formation of aircraft, the beating which results from their incomplete separation can be used as a means of estimating the number of objects thus incompletely resolved.

The First Steps

When it became distressingly obvious that it would be important to detect and locate enemy aircraft while they were still far from our shores, the high probability that a single aircraft could be located at a hundred miles, and the possibility that it could be detected at two hundred miles, was readily demonstrated by simple arithmetical process, supported by a crude experimental demonstration at short range. The arithmetic was easier than the consequent decision, for it pointed to an engineering efficiency, in a single determination, of the order of one in 10^{17}. The joint operational and technical decision that it was alike worth while and practicable to utilize this low-efficiency process transformed an idle dream, often conceived and always dismissed, into a decisive weapon of war.

But there were many technical difficulties in the transformation. No distances less than thirty miles had ever been measured by radio range-finding; targets separated by less than fifteen or twenty miles would not be resolved by the then existing technique. These two profound and indeed prohibitive limitations must be removed by a very drastic shortening of the emitted pulse, from the then current durations of about half a millisecond to durations of five or ten microseconds. This shortening must be accompanied by a great increase in the peak power emitted, and by a 'squaring' of the pulse shape. A sharp leading edge was vital to accurate range-finding; a long trailing edge was fatal to echo separation. The receiver and its associated aerials must give good response over the wide frequency band occupied by such short steep pulses, and it must also be immune from paralysis by the enormously powerful impulses from a transmitter a few yards away; many other defects in senders and receivers had to be cured. No direction-finder of adequate sensitivity existed; it had to be developed. The effective measurement of flying height depended on specially favourable topography; sites with a favourable foreground must be combined with accessibility and bearing capacity for heavy towers. Even on the most suitable sites the resulting data had to be corrected against calibration flights and had, after correction, to be put in a form convenient for immediate communication to the user. How the technical problems were solved must be told in detail elsewhere; the broad operational results have already been outlined in the daily Press. Here it is important to emphasize the milestones in radar technique, and how they were set up.

Milestones

When the more obvious of the difficulties just enumerated had been surmounted there remained those due to interference between the rays propagated directly between ground station and aircraft, and those reflected, with an almost complete reversal of phase, from the ground. It was the presence of the reflected ray that made height-finding practicable; but this one convenience was a part compensation for great inconveniences. The phase reversal meant that the interference pattern between direct and ground-reflected ray had a minimum in the horizontal direction, so that low-flying aircraft could come close inshore before detection. The only cure for this was the adoption of much shorter wave-lengths, so that the bottom lobe of the vertical polar diagram could be pushed lower without the use of prohibitively tall aerial systems.

The higher minima in the interference pattern were still at such angles that there were inclined lanes down, or to some extent across, which aircraft could fly unlocated, and these gaps in coverage had to be filled by the use of aerials of different height, with a non-coincident interference pattern, and by switching frequently from one aerial height to the other.

The attainment of high powers and adequate receiver gain on one-and-a-half metre wave-lengths allowed low cover to be established; but it permitted also the setting up of the third milestone in radar. The aerial system for such wave-lengths could now be rotated mechanically, and gave a comparatively narrow beam. By electrical beam-swinging the beam could be moved by a few degrees, and by matching amplitudes of response with the beam in its two positions the target could be located in azimuth with an accuracy some twenty times greater than by the previous methods. The inaccuracy of bearing fell from one or two degrees to five or ten minutes of arc. This was indeed a landmark in the history of precision measurement by radio.

Concurrent work on improved accuracy in the time-delay measurement was in train, and it was soon (in fact in 1938) established that the operational range-accuracy of the monostatic radio range-finder was, against quick-moving aircraft targets at least, higher than that of the monostatic optical range-finder. Errors of about twenty-five yards at heavy anti-aircraft gunnery ranges became standard.

One of the greatest steps in radar technique was the development of the Plan Position Indicator. Initially the time-base of the cathode ray oscillograph had been a fixed diameter of the tube-face, and the radio response or echo made an indentation (or 'blip' !) transverse to this line. But when the rotating antenna was introduced, and the radiation was confined to a comparatively narrow rotating beam, it became practicable to make the time-base a radial one, with its zero at the centre of the tube-face, and to rotate it synchronously with the antenna. If now the received signal were used to give brightness modulation of the cathode-ray beam, a response was displayed as a bright, though not very small, sector of a circle, the inner edge of this sector measuring the range and the mid-angular point of the sector the bearing; the width of the sector was of course governed by the sharpness of the radio beam. Thus automatically the rotating radial time-base gave in map form a plan display (with slant range used instead of horizontal range) of the positions of responding objects. This device, first used in the controlling from the ground of night-fighters, was of the utmost importance in the airborne and shipborne radar of the war against the U-boat, and in the aids to the bombing of invisible targets which were variously called 'H2S', the 'gen-box', 'Mickey' and the 'Magic Eye'.

The greatest revolution of all, however, was the success of the campaign for centimetric wave-lengths. It had long been clear that the major defects of airborne radar, and many of those of ground radar, were curable only by the use of an extremely fine pencil of radiation scanning the area to be explored. Such a pencil could only be formed by an antenna and reflector system having an aperture of many wave-lengths, and this could only be fitted in aircraft if the linear dimensions and weight were kept down by the use of wave-lengths less than ten centimetres. The precision with which individual targets could be located, the clarity of display, the separation of responses from two or more targets, and the reduction of the very serious overlaying effect of responses from fixed objects were all immediately dependent on the attainment of centimetric working. There were some associated advantages in reduction of the enemy's power to interfere with the full enjoyment of radar facilities.

How centimetric radar came is so closely associated with the general story of the organization of scientific effort on radar that it is desirable to look next at that story.

The Spiritual Ingredients

The most important thing about the British development of radiolocation as an instrument of war is not that it happened, but that it happened at the right time. The essential difference between the British effort and the most nearly corresponding effort in other countries is to be sought in those intangible factors which assured to us, at each stage in development, an adequate (though often a no more than adequate) margin of time for meeting the successive crises of the War.

It cannot be too often or too firmly stated that the victory over Germany was essentially a victory of the spirit. No technical devices can turn the scale of war save as tools of the spirit. Nor is there, indeed, any real gap between spirit and material, though the very mechanical perfection of our new technical devices may hide the vital fact that they are not only the tools but also the products of the spirit. Radiolocation is perhaps the best of all examples of the interaction of spirit and technique in the forging of a decisive weapon of war. But its origins in the spirit of science may be temporarily lost to view behind its successes. The curiosity-value of its devices, the wealth of its applications to all forms of warfare, and its spectacular victories may dazzle the casual observer.

Radiolocation was the direct, but in no wise the predestined and inevitable, fruit of pure research. Its beginnings lay in the work of those who laboured to understand more of the things that happened in the earth's atmosphere. Its later developments, and much of its technique at all times, were due to those who sought the inner secrets of the structure of matter.

Britain was a prominent leader in those pure researches into the physical processes of the ionosphere and of the lightning flash which were, indeed, directed towards the improvement of radio communications, but which were of an enlightened width and depth, not closely trimmed to immediate practical ends. These researches were State-aided, but most generously and most lightly State-controlled. The Department of Scientific and Industrial Research had, through the vision of its first Minister, A. J. Balfour, and of its successive administrative heads, Sir Frank Heath, Sir Henry Tizard and Sir Frank Smith, established a unique position for its Radio Research Board, founded and nurtured by the gentle wisdom of Admiral of the Fleet Sir Henry Jackson. Among the Board's contributions to the international stock of fundamental knowledge and to the international store of radio technique, none was more important than those due to Dr. E. V. Appleton, whose radio researches it supported from its foundation until the time when he succeeded Sir Frank Smith (himself a dominant figure in the scientific work of the Board) as Secretary of the D.S.I.R., and became Sir Edward Appleton. It is morally certain that without the peaceful pursuits of the Board in general, and of Appleton and his colleagues in ionospheric research in particular, radiolocation would have come too late to have any decisive influence in the War.

The Radio Research Board had trained a team of young research workers encouraged to see and explore the wide open spaces between the Morse key and the loud-speaker. They were to remember the needs of the radio user, but to probe to the heart of the processes rather than to apply palliative dressings. They were to be pathologists rather than physicians; to be physiologists and even morphologists rather than pathologists. Their vision and imagination were to be turned in the general direction of application, but they were to take neither narrow nor short views.

The scientific staff of the Air Ministry reviewed in 1934 the prospects of aerial warfare. They were profoundly disturbed by the lack of any effective means of defence against the fast military aircraft of the day. On their advice, the Secretary of State for Air sought the counsel of three distinguished 'outside' scientific workers of deep knowledge and wide experience. They in turn suggested that one aspect of the problem should be discussed with a member of the Radio Research Board's team.

As an official document has recently said: "This contact between a user Department with a great need, and a Department which had fostered scientific discovery not wholly directed towards specific needs, was perhaps one of the most important events in our history, and illustrates the need for fostering scientific research in all fields and for making the needs of the State known to those who are engaged on scientific research".

It was a characteristic and natural step in this train of enlightened reviews of general needs rather than particular prescriptions, that the radio researcher brushed aside the problem directly posed, replacing it by a quite different and far from novel problem, for which he proposed a novel solution. The solution was novel, not because it had not been glanced at qualitatively on other occasions, not because it contained any intrinsically novel element, but because it was a quantitative synthesis, a judicious mixture of old ingredients, each ingredient to be modified and refined for the new purpose, and adapted to the complexities of an operational problem far more involved than those of the laboratories—even of the open air laboratories—in which the ingredients had been evolved.

But again it must be said that the basic ingredients of radiolocation were in fact the spiritual ingredients, the wisdom that integrated the scientific advisers into the Air Staff in the handling of its day-to-day worries, the judgment that assessed the relative priority of these worries, the courage of all the participants—courage in the small band of "good but not first rank" (the description is their own) men of science who made firm promises out of their exact knowledge and their imaginative enthusiasm; courage in the men of science who recognized the scientific and operational validity of promises made on a one in 10^{17} basis, courage in the officers who staked some millions of pounds of public money and revised the air defence system of the country on the paper promises of a "bunch of scientists", the exploits of a "rather ancient lorry" near Daventry and the not unqualified successes attained in a few tentative air exercises.

That success—a success which even in the first trial of strength in 1940 made the difference between a free and an invaded Britain—was achieved was due to those same influences which governed the acceptance of the gamble. The most significant factor in the story of radiolocation was not the technical skill packed into its boxes, was not the operational skill with which they were used. It was the unprecedented and unprecedentedly productive interplay between scientific and operational minds, which carried the basic technique from its first defensive application in an early warning system through more actively defensive phases to a wealth of offensive applications which had a decisive effect in every major phase of the War.

When radiolocation has taken second or third place to future novelties in the military art, this intimate co-operation of scientific and military minds will remain as the real secret weapon in the British armoury, as something which grew to full vigour with radiolocation, at once a source and a product of that successful development. Nowhere in the councils of the United Nations or of their enemies—and those concerned in developing radiolocation have been at some pains in recent months to verify this last point—has there been a parallel to the practice followed from the first days of radiolocation research. The Air Marshal took advice from the junior scientific officer on how to make war, and the laboratory assistant was told by the Admiral why physics has sometimes to give way to psychology in the planning and conduct of operations. The soothing fiction of an operational requirement stated by an all-wise staff, and unquestioningly satisfied by a docile and technically expert developer, has no place in the history of the most versatile technique of the War. The proud and affectionate title of "Boffin" conferred on the scientific developer by his military colleagues and co-workers is earned only by a man in whom technical expertize is matched by operational understanding and indomitable zeal, allied to the peculiarly scientific virtues of inquisitiveness, impatience, intolerance and insubordination.

The fruitful co-operation was not confined to the origination and development of technical equipments and systems. It extended to the selection and training of personnel to operate and maintain the systems, to the evolution and practising of tactical methods based on the systems, and to the whole complex of technical, tactical and logistic problems involved in introducing new scientific devices into heavily engaged operational formations.

The over-riding demands of secrecy limited the size of the team and the facilities that could be devoted to radiolocation in the 1935–39 period. Not the least of the merits of that limited team were their technical restraint and their ruthless objectivity, their refusal to explore at once the innumerable avenues of development opened by the new art, their insistence on the sacrifice of refinements, elegances and versatilities to the one desperate need for "something to be going on with". They never turned aside from their cult of the third best—"the best never comes, the second best comes too late".

Easter 1939 saw the opening of a continuous watch—sustained unbroken for the next six years—by the radar stations of the east and south coast; it saw also the reinforcement of the research and development teams by the cream of the physical research laboratories of the country. The ninety physicists who spent the spring and summer of 1939 in the coastal stations devoted their first war-time efforts to meeting the needs and exploiting the possibilities which suggested themselves in their first scrutiny of radar at work. Further strengthened by transfers from other groups, the greatly augmented team brought to the work intellectual qualifications, research experience, depth of fundamental physical knowledge, imagination, initiative, versatility, enterprise and enthusiasm, inquiring and critical faculties, of quite unique order. The dreams and aspirations of the 'founder members' were rapidly fulfilled and surpassed, new dreams were converted to achievements, and the traditions of constructive debate between General and junior scientific worker and of inextricable interweaving of contributions from operational officer and boffin were cherished, maintained and extended.

The newcomers, knit into a large and powerful organization, with facilities better proportioned to their needs than ever before in research for military purposes, came from other fields besides pure physics. Chemists, physiologists, general biologists, dons and schoolmasters were united by certain basic characteristics common to all branches of science. The habit of measurement, classification, comparison, and orientation in the light of defined principles, the isolation of those changes in behaviour which are due to the variation of one identified factor from those due to other factors, the stringent assessment of statistical validity in measurements, are of the creed of all men of science in all fields. A sturdy refusal to take refuge behind chance and accident, a firm hatred of the creed of the 'magic box', make the boffin the sworn enemy of the 'gremlin'. A stern exclusion of emotion from the method of science is allied with a fierce flame of emotion as the motive power behind the application of that method. Above all, a religious conviction that all facts are good facts, that suppression of the known and measurable truth is the supreme sin, governs and explains the determination of the man of science to drag every strategic and tactical skeleton out of the cupboards of the Commands, so that it may either be reclothed and revivified or be decently interred.

From this fervent objectivity, backed by the highest technical skill ever organized into a single team, and by a remarkable organization for quick production, came the successive devices that turned the tide of battle in successive phases of the War. They were vital to the defeat of the day bomber and the night bomber attacking London and other British cities and towns. They drove the enemy surface ship from the Straits, the North Sea and the oceans of both hemispheres. They beat the U-boat in the Bay of Biscay and in the Atlantic. They foiled the 'flak' gunner in the Ruhr. They penetrated the fog and cloud cover that was the best anti-aircraft aircraft defence the German cities ever had. They baffled the night fighter which strove to make good these lost defences. They silenced the coastal gunner on the

Normandy shore. And, by aiding the airborne forces and the tactical air forces supporting the armies of liberation, they contributed to the defeat of the last Panzer and infantry defences of the crumbling Reich.

The Centimetric Revolution

The demands for adequate transmitter power and receiver sensitivity on centimetric wave-lengths had grown more and more insistent from the time they were first voiced by the radar team of 1935, and the ninety 'scientific observers' on the chain in 1939 included those best qualified to perceive the intensity of the need and to devise the means for meeting it.

Under the inspiration of Prof. M. L. Oliphant a team at the University of Birmingham provided the essential element in the solution. Dr. J. T. Randall applied the resonant-cavity technique to the relatively ineffective magnetron of pre-war days, and made of it a radically new and immensely powerful device which remains the heart of every modern radar equipment. Dr. R. W. Sutton, of the Admiralty Signals Establishment, matched it with an equally novel receiving valve, the Clarendon Laboratory team made a vital contribution to the efficient use of a common aerial system for transmission and reception of radar pulse signals, and centimetric radar for ground, ship and airborne use was at hand. Floodlighting and wide-beam systems remained an essential part of the whole radar complex; but the fine pencil scanning systematically and point by point the whole area of search alone sufficed to paint the fine detail of target areas, to avoid the smudging over of each element by the response from adjacent or more remote elements, to give adequate 'illumination' of the extremely low flier or the surface ship by coast-watching stations. And apart from permitting fine-beam formation, the very high frequency permitted a corresponding improvement of discrimination in depth, by allowing pulses of duration much under one microsecond to be formed by the transmitter and reproduced comparatively faithfully by the receiver. Only at frequencies of, or above, three thousand megacycles per second does the bandwidth occupied by such short pulses constitute a sufficiently small percentage of the central frequency for good pulse-shaping at sender and receiver to be attained.

These were the foundations of the techniques which gave the night fighter an A.I. set in which the returns from the ground no longer overlaid those from the bomber under pursuit whenever its range from the fighter exceeded that of the nearest ground, so that the maximum effective range of the A.I. set was no longer, as before, the flying height of the fighter. They gave the searcher for the surfaced U-boat, in destroyer, corvette and aircraft, the means of locating a periscope at several miles and a normally surfaced U-boat at tens of miles, and prevented the U-boat from getting, before he was driven from the sea, that early warning of pursuit which he derived from listening sets on metric wave-lengths. They gave the anti-aircraft gunner a higher precision and an almost complete release from the limitations of site and obscuration by 'ground-clutter' which had crippled his tactical freedom in using metric-wave GL sets. They were applied by our American collaborators in ground installations of considerable elegance and high adaptability which made great contributions to the defeat of the flying bomb and to the close air support of ground forces in the liberation of Europe.

Bombing by Radar

Perhaps the most picturesque, and certainly one of the most valuable, of the centimetric radar devices is the 'H2S' airborne aid to the bombing of invisible targets. The 'P.P.I.' picture in which seas, lakes and waterways remain black because they give substantially specular reflexion of the scanning pencil away from the aircraft projecting it; in which coastlines, with their cliffs, bays and inlets, show up clearly as outline map features because they scatter radiation back towards its source; in which the inland landscape is of a nondescript intermediate tone; and in which the 'works of man'—camps, hangars, and above all towns and cities—stand out brightly, the towns reasonably clearly defined in outline at tens of miles and in some detail at ten miles and under; this fascinates everyone at first acquaintance and never ceases to impress even the hardened boffin.

It has no competitor in this grip on the imagination, save perhaps the other blind-bombing device, of higher precision but limited coverage, called 'Oboe'. That two controllers sitting in vans on English soil should each know with an accuracy of a few yards each way—certainly within fifty yards—the position of an aircraft over Essen is a surprising thing, no more and no less surprising when one reflects that they know it much better than do the occupants of the craft. Yet in principle it is ridiculously simple; one ground station, *A*, knows the deviations of the craft from a circular track of constant distance from *A*; the other, *B*, knows when the craft flying a circle about *A* is at any desired distance, including zero distance, from the intersection of that circle with another of known radius about *B*. And this point of intersection was selected, in the relative comfort of the English ground stations, to be the bomb-release point, arrived at by applying up-to-the-last-moment corrections for the local wind conditions over the German target. *A* and *B* are pulse-interrogator stations, the aircraft has a responder of constant and accurately known delay-time, and meticulous calibration and adjustment assure an accuracy in radar range finding of one in ten thousand or so at some two hundred miles.

Radar in Peace

Radar in war fell into three convenient categories, each of which has come to stay in the peace.

Primary radar is that form of radar which "does not require the co-operation of the object to be located". It is useful against icebergs and enemies generally; it is an extravagance when used against friends.

Secondary radar requires that small measure of co-operation which is involved in the fitting and switching on of an otherwise automatic responder. The responder sends back, when interrogated by radar pulses, reply pulses on a different wave-length —so that 'ground clutter' disappears from secondary radar—coded with information about the 'personal identity' of the craft carrying the responder, and about its flying height if it is an aircraft.

Radar navigation does not depend essentially on the return of an echo, amplified or unaltered, from the craft to be located. It may in some special cases like 'Oboe' find that convenient; in some other and more frequency cases like 'G-H' and 'Babs' (Blind Approach Beacon System) and 'Rebecca-Eureka' utilize coded responses sent back by a ground responder-beacon in reply to pulses from an airborne or shipborne interrogator. And in 'Gee' and 'Loran' and related systems it will depend on a measurement in the craft of the time-difference of arrival of primary pulses from synchronized ground stations in accurately surveyed positions.

In a well-ordered world—which includes, but goes beyond, a world at peace—primary radar would have no place in aviation save as an airborne means of avoiding dangerous high ground and dangerous clouds and as a 'last resort' ground system for locating aircraft whose responders had failed, as they may on occasion do even in a well-ordered world. In the shipping world it would have a corresponding role, save that all ground is then dangerous high ground and the iceberg is the equivalent of dangerous cloud. In land transport primary radar should have no place at all; but primary radar on the ground will help the meteorologist in his still difficult task of forecasting. The world has still some way to go before even an optimist will regard it as well-ordered, and so ships will sail and aircraft fly with primary radar performing other duties which will ultimately be better confided to secondary radar.

The aim of the radar aids to civil aviation which were discussed at the recent Third Commonwealth and Empire Conference on Radio for Civil Aviation (C.E.R.C.A.) in London is to give from a generous provision of ground installations and the minimum of equipment in the aircraft, sufficient information (without the intervention of communications from ground controllers) for the pilot to know at every moment where he is, how to fly to his destination by the shortest or safest route, and how to land safely whatever the visibility. These provisions will be supplemented by radar aids which will keep the air traffic controller fully informed of the traffic pattern around his airport and on his designated routes. It will not be done cheaply, but independence of the weather has never been cheaply bought.

The simpler problems of marine transport find simpler radar solutions, and the sea and air transport without which our great Commonwealth and Empire cannot hold together in its service to civilization need radar services with an urgency second only to that which produced radar services in war.

Of railroad radar no one will at this date speak with equal confidence. But it is surely reasonable to believe that the simple elements of secondary radar in cab, cabin and caboose will at last banish the primitive detonator from this fog-girt isle! Romance cannot wholly dispense with radar in its noble task of bringing up the eight-fifteen—especially in the not infrequent conditions in which it is not romance alone that is 'all unseen'.

SCIENCE IN THE U.S.S.R.*

ASTRONOMY AND TERRESTRIAL MAGNETISM

By Sir HAROLD SPENCER JONES, F.R.S.

Astronomer Royal

RUSSIA has played an important part in the development of astronomy since the foundation of the Pulkova Observatory by Czar Nicholas in 1839. Under the direction of F. G. W. Strüve, this observatory was built regardless of expense. It has made notable contributions to fundamental astronomy, its instrumental equipment for such observations being more varied and complete than that of any other observatory. The Pulkova observations have always been characterized by their great accuracy. At the beginning of the present century, the work was expanded to include astrometry and astrophysics. Its great refractor, of 30-inches aperture and 45-feet focal length, was one of the finest in the world. In 1908 an astrophysical observatory was established at Simeis in the Crimea. There were, at the time I visited Russia in 1914, several other observatories, but for the most part their equipment was modest and their staffs were small. Since the Revolution a great expansion in astronomical work has occurred. Additional instrumental equipment has been installed, including the 40-inch reflector at Simeis: new observatories have been constructed in Abastumani (Georgia), Stalinabad (Tajikistan), Yerevan (Armenia), Pòltava (Ukraine) and Alma Ata (Kazakhstan), the last of these during the war years. Astronomical institutes have been established in Moscow and Leningrad, for computational and theoretical work in the fields both of astrophysics and of celestial mechanics. The total staffs have been increased about ten-fold.

In the pre-Revolution days, each observatory worked alone, and its resources were generally insufficient to enable large programmes of observation to be undertaken. In the Soviet years an Astronomical Council has been constituted by the Academy of Sciences which co-ordinates the work of the various observatories, including both those which come directly under the Academy and those which are attached to universities. Thus, it has been possible, by pooling of effort, to undertake fields of work which are beyond the scope of any single observatory and also to avoid unnecessary duplication. For example, observations of selected minor planets and of the positions of some 16,000 red giant stars have been undertaken at several observatories for the improvement of the fundamental system of star places. Special attention has been given to solar phenomena and their terrestrial relationships. The paths of totality of the total solar eclipses of 1927, 1936, 1941 and 1945 have crossed Soviet territory and extensive programmes of observation were planned. For the last three of these eclipses some fifteen to twenty expeditions were organized and were distributed along the line of totality—valuable results being obtained.

The time service has been extended, and its accuracy considerably improved. A Nautical Almanac is published to meet the needs of navigators and surveyors as well as astronomers. The computations for its production are made at the Astronomical Institution in Leningrad.

Soviet astronomers have made important contributions to the theory of the structure of comet tails and heads, to the problems of the variation of latitude, to the study of the atmospheres of stars (including the discovery of heavy isotopes of carbon), to the problems of novæ, and to cosmogony.

Astronomy in the U.S.S.R. has suffered a serious setback through the destruction of, or damage to, various observatories. The Pulkova Observatory was in the front line for two and a half years in the fighting around Leningrad and has been completely destroyed by German shelling and bombing, though some of the instruments were saved. Most of its valuable astronomical library, probably the most complete in the world, has been lost; some of its treasures, including the manuscripts of Kepler, were fortunately saved. Its destruction was no doubt inevitable in the circumstances. But it was otherwise in the case of the Simeis Observatory, for no fighting took place in its vicinity. The Germans removed the telescopes (which have since been found in Potsdam, but in a state unfit for use), most of the library and most of the astronomical negatives; they then deliberately set fire to and destroyed the Observatory. The Observatories at Odessa, Kiev, Nikolaiev, Kharkov and Poltava were all badly damaged. Many of the observational records have been removed or destroyed, so that some of the co-operative programmes of observation, on which much work had been done, will have to be commenced anew. Many of the astronomers and some of their instruments were evacuated far into the interior. Some of the Pulkova astronomers were moved from Leningrad by aeroplane during the siege. Throughout the War a considerable amount of research in astronomy was continued in spite of the difficulties of the conditions.

---

* Continued from page 285.

The reconstruction of some of the damaged observatories has already been commenced. Plans have been prepared for the rebuilding of the Pulkova Observatory according to its original plan; the telescopes which were saved will be replaced in their original positions. But new additional instruments will be installed. Plans are under consideration for the establishment of a large astrophysical observatory in the Crimea, provided with powerful reflecting telescopes and with instruments of modern types; there may be also a subsidiary station somewhere in the southern hemisphere.

Mention may be made of the invention by Dr. Maksutov during the War of the new system of meniscus lens telescopes which, because only spherical surfaces are employed, are simple to manufacture. These telescopes are powerful and extremely compact. The largest meniscus telescope as yet constructed is of nine inches aperture; but telescopes of this type and of greater aperture are to be constructed for astronomical observation.

It is certain that the U.S.S.R. is destined to play a prominent part in the development of astronomy in the post-war years.

The Institute of Terrestrial Magnetism, established in Leningrad in 1940, embraces a wide field of work. It comprises sections for land magnetic surveys, sea magnetic surveys, magnetic observatories, magnetic cartography, ionospheric and cosmic ray observations, and theoretical investigations. Nineteen permanent magnetic observatories, including some high-latitude stations, were in operation when the War started. Six of these at Yanov, Stepanovka, Novgorod, Amvrossievka, Nizhnedevitsk and Pavlovsk were occupied by the Germans in 1941–42: same of the staffs were evacuated and some were made prisoners. When the Germans retreated they burned or blew up the observatory buildings in Pavlovsk, Novgorod and Nizhnedevitsk. Observational records and instruments were removed or destroyed. The magnetograms of the Second Polar Year stations have disappeared. Profs. Weinberg and Trubyatchinsky died of famine during the siege of Leningrad. Magnetic survey work has been continued during the War, and some expeditions were sent to the north of Siberia. Observations are made at regular intervals at a number of repeat stations for the determinations of secular changes. Magnetic anomalies associated with possibly useful mineral deposits have been studied. Solar, magnetic and ionospheric data are collected and summaries are published in ten-day cosmic bulletins.

The Institute is to be moved to a site near Moscow, where special buildings are to be erected, and the magnetic observatories destroyed by the Germans are to be re-established. Theoretical investigations in terrestrial magnetism and allied subjects are also carried out at the Institute for Theoretical Physics in Moscow, where Prof. Frenkel has recently developed new theories of atmospheric electricity and of the earth's magnetism. Among other work undertaken at this Institute are theoretical investigations of the scattering of light in the earth's atmosphere and of atmospheric transparency, and the study of the light of the night sky.

THEORETICAL PHYSICS

By Prof. M. Born, F.R.S.

University of Edinburgh

In the original group of British delegates to the Moscow conference, theoretical physics was well represented (Darwin, Dirac, Mott and myself); but I was the only one allowed by the Government to proceed. The following account is therefore based only on the observations of one pair of eyes and ears, which had to absorb a multitude of impressions vastly more interesting and important than even the most fascinating scientific things: a new and strange type of civilization in its various activities, social, economic, military, scientific, artistic, etc.

Theoretical physics can scarcely be separated from physics in general, on which Andrade has reported in a previous number of *Nature* (August 25, p. 223). I shall add a few remarks to his excellent account, but speak mainly about the more abstract branches of my subject. As the Soviet State is based on a definite philosophical system, the question arises whether this fact has any influence on the development of fundamental ideas in physics. I have found scarcely any traces of such an influence, and certainly no restrictions of research. The Russian physicist interprets the facts of observation in the same spirit of intellectual freedom as his Western colleague, and indulges in any speculation on cosmology, relativity or quantum theory without being censored. Nor does the question of the practical applicability play a great part, as many of the reports on other subjects have already stressed. Fundamental research is acknowledged as the basis for a sound growth of science, and a theoretical physicist is no more expected to produce results of economical importance than the roots of an apple tree to bear fruit; but if the roots are allowed to spread freely the branches carry a good crop.

The theory of relativity has a powerful representative in V. A. Fock (Moscow). A most important paper of his which appeared just before the War (February 1939) is little known in Britain. It contains the solution of the fundamental problem, also treated by Einstein (and collaborators), whether the field equations of gravitation are sufficient to determine the orbits of planets, or whether separate equations of motions are necessary. Fock's answer is that no such assumptions need to be made; he obtains Newton's laws as a first approximation for small bodies separated by large distances and develops the relativistic correction terms. I had a short discussion with Fock on Mises' foundation of the theory of probability and found him very sceptical: to define probability as the limit of relative frequencies in an actual series of trials seems to be a vicious circle, for there is no certainty of the existence of such a limit, but only a probability. I think Fock is right. He is also a great expert in quantum mechanics. I found him and the other Russian physicists perfectly acquainted with the newest developments, in particular of the theory of quantized fields and its application to radiation and mesons. J. Tamm (Moscow) and J. Frenkel (Leningrad) are working on these problems; their attitude to the well-known difficulties and perplexities is not much different from my own. To mention only one point, they are not satisfied by Eddington's ingenious theory of ultimate particles. Among the many other questions we discussed, I wish to direct attention to Frenkel's dynamic theory of atmospheric electricity, which has just appeared and seems to me very promising. As Andrade has already pointed out, Frenkel is attached to Joffe's laboratory in Leningrad and takes an active part in the interpretation of the experiments on semi-conductors and other things.

In an account of theoretical physics, the theoretical part of physico-chemistry cannot be excluded. In Moscow it is brilliantly represented by Frumkin, in whose laboratory well-planned work is done on the chemistry and physics of surface layers.

Russian physics suffered a great loss last year by the death of Mandelstam who, together with Landsberg, discovered almost simultaneously with Raman and independently the phenomenon since called the Raman effect. Mandelstam's optical school is continued under Landsberg's leadership. Another member of it is E. Gross, who discovered the splitting of spectral lines in a beam of light which is scattered by a liquid or a crystal, an effect due to the Doppler effect produced by the reflexion of the light waves on sound waves.

Russian physicists were very keen to learn something about work done in Britain, and I had to give several lectures. One of these was in the Lebedev Institute of Physics, the director of which, S. Vavilov, has just been elected president of the Academy of Sciences of the U.S.S.R. This visit gave me the opportunity of a glimpse of the celebrated laboratory and a discussion with its workers on diverse problems.

The limits of this article do not allow me to give an account of new discoveries in crystal physics and their explanation. I must, however, add a few remarks to Andrade's description of Kapitza's Institute for Physical Problems and the work done there. For this Institute contains a separate group of theoretical physicists under Landau's leadership who have made essential contributions to the low-temperature work going on. Kapitza himself is an expert in thermo-dynamics, which he applies as an engineer to the technical problems of the liquefaction of air, and as a physicist to research on liquid helium. It is most remarkable and characteristic of Russian science how applied and pure physics, experiment and theory, are here combined. Andrade has mentioned Landau's theory of superfluidity which was published in 1941, but has been improved by him and his collaborators. It will cause the theorists some 'headaches'; for though it is most successful in predicting experimental results, for example, the existence of two different velocities of sound (the normal one of about 220 m./sec. and a slow one of about 20 m./sec.), it also contains many obscurities. The first part deals with the quantization of the hydrodynamical equations for ideal liquids. The second part describes helium II as a mixture of two phases, or interpenetrating liquids, one having viscosity, the other not. This new and surprising idea is clear in itself but scarcely connected with the first part. The link is a consideration about the quantization of vortex motion, which leads to the conclusion that the range of energy states (of the whole liquid) consists of two parts separated by a gap $\triangle$, one part representing the irrotational, the other the vortex motion. The existence of this finite energy $\triangle$ prohibits, for slow motions of the liquid, the excitation of quanta, therefore the transfer of momentum from the walls, and this means lack of viscosity. Landau gives an expression for $\triangle$ in terms of density ρ, mass of the atom m and Quantum constant $\hbar$; the formula as published is wrong, but the idea is right. One has simply to remember the well-known expression for the so-called degeneration parameter from the Einstein-Bose or Fermi-Dirac statistics, $A = n\hbar^3/(m\triangle)^{3/2}$ where $n = \rho/m$ is the number of particles per unit volume. If $\triangle$ is expressed in terms of a critical temperature T_0, $\triangle = kT_0$, then for $T_0 = 1°$ K. the dimensionless quantity A is very small for a gas, but of the order unity for a liquid*. Hence quantum effects can be expected for every liquid at temperatures of the order 1° K., but are only observable in helium as all other substances become solid at such low temperatures. Landau shows how the actual value of $\triangle$ can be determined from measurements of specific heat and finds that it is 8–9° K. This value is then used for further calculations, for example, of the two velocities of sound.

There are many other interesting investigations which I should like to discuss; but I have first to digest the reprints which were given to me in considerable numbers.

I cannot close this report without expressing my thanks to the Russian colleagues for the kind reception and hospitality we found in their midst.

(*To be continued.*)

---

* Landau's formula should read

$$\hbar^2 \rho^{2/3} m^{-5/3} = \hbar^2 n^{2/3} m^{-3/3} = A^{2/3} \triangle.$$

OBITUARIES

Colonel C. H. D. Ryder, C.B., C.I.E.

COLONEL CHARLES HENRY DUDLEY RYDER died on July 13 at Bognor Regis at the age of seventy-seven. He was the seventh son of Colonel Spencer Dudley Ryder and was educated at Cheltenham College and the R.M.A. Woolwich, whence he received a commission in the Royal Engineers. After the usual courses of instruction at Chatham, he proceeded to India and was posted in due course to the Survey of India, in which the whole of his subsequent career was spent.

Much of Ryder's earlier work up to the first World War was carried out on active service or deputation in China, Tibet, Persia and Turkey. Later he was placed in charge of frontier surveys in India, and after taking command of the Survey Service in Mesopotamia during 1917–18, he succeeded Sir Sidney Burrard in the latter year as surveyor general of India, retiring from that post in 1924.

Ryder's greatest contributions to geography were in the field of survey and exploration in China and Tibet. In 1895, not long after joining the Survey of India, he served on the Mekong Boundary Commission, demarcating the Burma-Indo-China frontier. During 1898–1900, with Major Davies, he surveyed most of the routes in the Yunnan Province of China and in parts of Szechwan. Their journeys ended in a voyage down the Yangtse River to Shanghai, and their work forms the basis of present-day maps of these regions. In 1901–2 he was again in China as a survey officer with the Chinese Expeditionary Force. After a brief interval in India, he joined the Tibet Frontier Commission in 1903 and Sir Francis Younghusband's mission to Lhasa (1904). Taking advantage of the newly imposed treaty terms and of the presence of British troops, Ryder was given a free hand to carry out exploration in southern Tibet, and accompanied by Captain Rawling and a very small party he travelled westwards up the Tsangpo valley, exploring and surveying many thousands of square miles of, for the most part, unknown country. They fixed the sources of the Tsangpo, Sutlej and Indus, surveyed Lakes Manasarowar and Rakas Tal, and the region of the holy mountain of Kailas. Their work was controlled by the positions of the Himalayan snow peaks to the south which had been fixed many years previously from the plains of India. A great number of additional peaks were fixed, and the claim that Mount Everest was the highest mountain, in any event in regions hitherto explored, remained unassailed. The expedition reached Simla by way of the Shipki Pass in January 1905; its results form by far the greatest single addition to knowledge of the topography of the Tibetan plateau.

In 1913–14 Ryder served as chief survey officer on the Turco-Persian Boundary Commission, and as deputy commissioner during the absence of Mr. Wratislaw in the later months. The demarcation of this long frontier was complicated by a number of intricate negotiations. For his explorations in China and Tibet Ryder received the Patron's Gold Medal of the Royal Geographical Society, the Silver Medal of the Royal Scottish Geographical Society, and the Gold Medal of the French Geographical Society, and he was awarded the C.I.E. for his work on the Turco-Persian boundary.

C. G. LEWIS.

Dr. Catherine Alice Raisin

DR. CATHERINE ALICE RAISIN, a pioneer who blazed many new trails, died at Cheltenham on July 13 at the age of ninety. Her early education was received at the North London Collegiate School, of which she always spoke with gratitude as being one of the earliest schools to start providing more serious education for girls. Miss Raisin continued as a teacher at her old school until 1875, when the opening of certain classes to women students was advertised by University College, London. Among these was a course in geology by Prof. Morris. Miss Raisin attended this class, and so became the first woman to take geology in the University. In the following year she joined Prof. Morris' classes in mineralogy, only to discover after the course was completed that it had not been officially open to women.

In 1878 the degrees of the University of London were thrown open to women, and Miss Raisin at once began to prepare for her B.Sc. After passing the Intermediate Science examination in 1879, she selected geology, botany and zoology as her three subjects. She attended Prof. Bonney's classes in geology at University College during 1880–82, and Prof. Bower's classes in botany. Attracted by Prof. Huxley's work in zoology, Miss Raisin obtained special permission from him, in 1883, to attend his classes at the Royal School of Mines. After graduating B.Sc. with honours in geology in 1884, Miss Raisin continued at University College as a research worker, and at the same time as a voluntary assistant to Prof. Bonney, who was then very much overburdened with work. She received her D.Sc. in 1898, and in 1902 was elected a fellow of University College.

During the years when she was preparing for her degree, Miss Raisin achieved one of her earliest ambitions by founding and organizing a discussion club for women—the Somerville Club—which foreshadowed the youth movement of to-day. The work involved must have seriously interrupted her studies, for when the Club opened in 1880 she had already enrolled a thousand members. Under her inspiring leadership, first as honorary secretary and later as chairman, the Club flourished actively for several years. Meanwhile, other educational amenities for women were being developed in London, and in 1887, having served its initial purpose, the Club was wound up.

During 1886–90, Dr. Raisin was demonstrator in botany at Bedford College for Women. In 1890 she succeeded Prof. Grenville A. J. Cole as head of the Geology Department at Bedford College, a position which she held, together with the headship of the Geography Department, until she retired in 1920. Her outstanding teaching and administrative ability are further evidenced by the facts that she was head of the Botany Department during 1891–1908 and was also vice-principal of the College during 1898–1901. From these additional duties she eventually resigned in order to give more time to the claims of geology.

The originality of Dr. Raisin's teaching was in no respect better shown than in her celebrated lectures on petrographic provinces, which became the more fascinating since they were illustrated by practical work on rock specimens of her own collecting from many of the classic areas of Europe and North America. She was a first-class petrographer, with a firm grasp of the optical properties of minerals—then quite exceptional. Rightly unbound by fashion in petrogenetic thought, as time has shown, she stood almost alone in Britain in stressing the work of Lacroix, Termier and Sederholm on granitization, even at the time when crystal differentiation was beginning to hold the field as a major petrogenetic process.

Dr. Raisin's published work includes a long series of petrological and stratigraphical studies, dealing with rocks from the British Isles, Europe, North Africa and India. Her first paper, concerned with the metamorphic rocks of South Devon, was published in 1887, and is notable as representing an early attempt to recognize and map metamorphic facies. Dr. Raisin is, however, best known for her detailed investigation of serpentines.

In 1893 Dr. Raisin was awarded the Lyell Fund by the Geological Society of London, being the first woman to receive any such recognition from this Society. At that time women were not even allowed to attend meetings of the Society, and Prof. Bonney received the award on her behalf. When in 1919 women were admitted as candidates for fellowship of the Geological Society, Dr. Raisin was elected a fellow.

Dr. Raisin will be remembered by her students, not only as a stimulating and enthusiastic teacher, who worked ungrudgingly to promote their interests, but also as a generous, brave and sympathetic woman whom they loved.

DORIS L. REYNOLDS.

Prof. H. E. Annett, M.B.E.

THE death occurred on April 11, 1945, of Henry Edward Annett, at the age of seventy-four years. Dr. Annett's scientific career was varied and his interests ranged over several fields—tropical diseases, bacteriology and pathology among them.

As an undergraduate at the University of Liverpool, Dr. Annett studied physics under Sir Oliver Lodge, but later, in spite of Lodge's persuasions to continue his work as a physicist, he decided to study medicine. After graduating in medicine, he was elected to an 1851 Exhibition and carried out research on tuberculosis under Robert Koch in Berlin. He was a member of the first malaria expedition sent to West Africa by the Liverpool School of Tropical Medicine in 1891, and during the following year he himself directed a similar expedition. In 1905 he led the Animal Disease Expedition to Uruguay, and in 1906 the Colonial Office Expedition to the West Indies. He was later appointed to the chair of comparative pathology at the University of Liverpool, an appointment which he held until 1911.

Dr. Annett then devoted himself to research in bacteriology, a field in which he became widely known, and for some years was director of the Bacteriological Research Department of Messrs. Evans, Lescher and Webb, in Runcorn. While there, he discovered the 'Liverpool' virus used for killing rats and mice. During the War of 1914–18 he was asked to study the effect on child health of milk preservation by the use of formaldehyde and the conclusions he reached, which were embodied in a Select Committee report, led to a legal ban on formol preservation. For this service he was awarded the M.B.E. The later years of his life were devoted exclusively to researches on cancer and allied problems, and he was occupied with this work up to the time of his death.

Dr. Annett's health had been declining for some years, and his unfailing kindness and encouragement, graced with a rare sense of humour, will be missed by those younger research workers who had the good fortune to come into contact with him.

SARAH BARNES.

Dr. W. Knoche

DR. WALTER KNOCHE, a well-known investigator on climatology, atmospheric electricity, geography and ethnology, died on July 3 at Buenos Aires. He was climatologist to the Servicio Meteorológico Nacional of the Argentine Republic, as a successor to the late Robert Mossman.

Knoche was born in Berlin on March 7, 1881, his mother being a sister of Paul Ehrlich, one of the pioneers of modern chemical therapeutics. Through his uncle's example, Knoche received a powerful stimulus towards medical and physiological problems, and indeed a great number of his climatological investigations were devoted to the relations between climate and man, animals and plants. He studied at Geneva and Berlin, as a pupil of von Richthofen in geography and von Bezold in meteorology. After a short scientific expedition to Bolivia, where he made an extensive series of valuable meteorological observations at the height of 5,200 metres, he became in 1910 the chief of the Meteorological and Geophysical Institute of Chile, a post which he held until 1916. A great number of his early publications deal with atmospheric electricity, based on his own observations on land and sea and on mountains throughout the vast area between Teneriffe and Easter Island, and especially South America. His expedition, in 1911, to Easter Island led him to begin a comprehensive study of its different geographical and anthropological problems, which he discussed in a valuable monograph.

During recent years, Knoche's chief interest was concentrated on phytoclimatology, the formation of deserts, colonization, classification of climates and general bioclimatology, and it is fair to consider him one of the pioneers of this new branch of science. He was the author, together with the late Vladimir Borzakov, of a book on the climate of Argentina, now in the press.

A more detailed review of Knoche's many publications, considerably more than two hundred in number and dealing with an unusually wide range of subjects, will be given in the Argentine journal *Ciencia e Investigación*.

OTTO SCHNEIDER.

Prof. F. von Wettstein

THERE will be general regret at the information, received from private sources, that Prof. Fritz von Wettstein has died recently in Germany.

Son of Prof. R. V. Wettstein, of the University of Vienna, he achieved as great an eminence as his father in the advancement of botanical and genetical science. Under Erwin Baur at the Kaiser Wilhelm Institut, Berlin-Dahlem, he undertook research work on hybrids and polyploids in mosses, and was one of the first to show the relationships and characteristics of polyploid forms. In 1926 he was appointed professor of botany in the University of Gottingen, where his energies built up the Botanical Garden to be a centre for the breeding of cacti and for investigations on various cryptogams. In 1933 he was appointed to one of the premier botanical chairs of Germany, that of the University of Munich; and later, on the death of Erwin Baur, he was called to take charge, I believe unwillingly, of the German plant breeding and botanical programmes that were under way at the Kaiser Wilhelm Institut at Berlin-Dahlem.

Of a quiet unassuming character, earnest and extremely enthusiastic on any subject relating to botanical genetics, his death, at a comparatively early age (about fifty-eight), is a great loss to science. What I remember most distinctly about Wettstein was his extreme friendliness and overwhelming hospitality to all with whom he came in contact; and despite a lack of English, his ability to overcome language difficulties when talking about his well-loved *Funaria hygrometrica* and *Solanum* chimæras.

F. W. SANSOME.

NEWS and VIEWS

Dr. W. F. P. McLintock: Director of the Geological Survey of Great Britain

THE appointment of Dr. W. F. P. McLintock to succeed Sir Edward Bailey as director of H.M. Geological Survey and Museum is especially fitting at this stage in the long history of that institution. Dr. McLintock's keen analytical mind, his long administrative experience and his gifts for effective planning and exposition, are now brought most opportunely to the re-organization of the Survey's peace-time activities. After graduating at the University of Edinburgh, Dr. McLintock joined the Geological Survey in 1907 as assistant curator in the Museum of Practical Geology. In 1911 he left the Survey to take charge of the Geological Department of the Royal Scottish Museum, where he was responsible for the exhibits of the Geological Survey in Scotland. In 1921 he rejoined the Survey as curator and became deputy director in 1937.

Dr. McLintock's research has been concerned with the crystallography, mineralogy and paragenesis of the rare minerals datolite and petalite from Cornwall, with topaz and beryl from Lundy Island, and with zeolites from the Tertiary lavas of Mull. Of especial interest is his account of the metamorphism of sedimentary rocks by the combustion of hydrocarbons in south-west Persia. He described the Strathmore meteorite. His most important contributions, however, have been concerned with geophysical methods of geological survey. In 1926 he proceeded to Persia to study, under the auspices of the Anglo-Persian Oil Company, field methods of geophysical survey; and later, in collaboration with Dr. J. Phemister, he executed a number of surveys—gravimetric and magnetic—over geological structures such as dykes, faults, unconformities and buried channels, in order to obtain data for the critical appreciation of the value of geophysical methods in geological surveying. Dr. McLintock undertook the replanning of the Museum of Practical Geology on its transference from Jermyn Street to the South Kensington site, and was responsible for the scheme of exhibition in the new Museum. The success of this Museum and its recognition as the foremost geological museum of the world are mainly due to his untiring and enlightened directive efforts. Geologists look forward with confidence to the speedy recovery of its former glories.

Mr. A. A. Kift

MR. A. A. KIFT, who has served for forty-three years with Marconi's Wireless Telegraph Company, Ltd. and during the last twenty years has been successively sales manager, assistant engineer-in-chief and contracts manager, retired from the Company's service at the end of August. Mr. Kift is one of the best known Marconi officials and is one of those engineers who joined soon after the Company's formation and may be said to be responsible for laying its foundations. Like many of those early wireless pioneers, Mr. Kift received his training as an electrical engineer at Finsbury Technical College. After a further specialized course at the Marconi Training College at Frinton, he was appointed to the erecting staff and was engaged in fitting some of the first half-dozen White Star liners which were equipped with wireless in and about the year 1902 at a time when a range of 50–100 miles with a coherer receiver was regarded as very satisfactory communication. After that, Mr. Kift's work for the Company, afloat and ashore, ranged from the Labrador coast to Varna on the Black Sea, with the erection of stations round the English coast interspersed with his foreign travel.

Institute of Fuel: Deputy Secretary

MR. REYNOLDS-DAVIES has been appointed deputy secretary of the Institute of Fuel. Mr. Reynolds-Davies received his technical education at University College, Cardiff, and the South Wales School of Mines. He has had a wide experience as a chemical engineer and fuel technologist for several years. His industrial experience was obtained first of all as chemist on the Coke Oven Plant of the Cambrian Combine, now merged with the Powell Duffryn Associated Collieries, Limited. He was later engaged as assistant with the late Dr. W. R. Ormandy on Power Alcohol and Petroleum Products. This work was followed by nine years as one of the chemical plant managers with the British Industrial Solvents, Ltd. For the past three years, he has held the position of manager of the Development Department of the Royal Ordnance Factory at Bridgend.

Carnegie United Kingdom Trust

THE thirty-first annual report of the Carnegie United Kingdom Trust, covering the year 1944, shows that the total expenditure on grants amounted to rather more than £71,000, the highest annual figure reached during the War. This includes £10,000 in aid of a post-war experiment to be undertaken in Shropshire, where a community house is to be established to serve partly as a residential college for short-term courses of adult education, but also as a focal point for cultural activities within the county. A special grant of £3,000 has also been made to Toynbee Hall to enable it to extinguish a deficit, largely on building account, the continued existence of which is due mainly to war conditions. A grant of £2,000 has been promised to the Council for the Promotion of Field Studies towards the initial cost of adapting and equipping a pioneer field centre at Flatford Mill, Suffolk (see *Nature*, **155**, 744; 1945). The largest block of expenditure during the year was on youth services, which took nearly £22,000 as against £23,000 in 1943. Grants to the headquarters of national youth organizations decreased by about £3,000, but club equipment grants increased by about £6,000 to £15,000. The Trust intends to continue for a further period its provision of grants in aid of the equipment of hostels and camps provided by national and voluntary youth organizations, under detailed conditions which have been communicated to the organizations likely to be concerned. Discussions with the National Association of Boys' Clubs have been proceeding during the year, and the Trust has agreed in principle to provide the capital sum required for the acquisition and the first stage of adaptation of a country house in which the Association proposes to set up a residential institution for standardized training. A report has also been requested by the Trust on periodical literature for juveniles, with the view of considering improvements in this field, and the report is to be prepared on its behalf and at its expense by the Research Department of the National Council of Social Service. The endowment income of the Trust amounted in 1944 to £122,801, and of this £80,366 was expended on grants and administration.

A New Approach to School Mathematics

WITH the re-classification of secondary schools in Great Britain under the new Education Act, there is an urgent need for the complete overhaul of the curricula of these schools. This is especially true in the case of mathematics, evidence of which is to be found in the recent reports on school certificate mathematics (Conf. Exam. Bodies and Teachers' Associations, 1944); on the teaching of mathematics to physicists (Mathematical Association and the Institute of Physics, 1944); and on sixth form examinations in mathematics (Cambridge Joint Advisory Committee for Mathematics, 1945). In suggesting an alternative syllabus to those in operation at present, the first-named report makes the significant remark: "The whole syllabus is inspired by a desire to bring mathematics more closely in relation with the life and experience of the pupil". Herein lies the kernel of the question, and it is symptomatic of the dissatisfaction felt at the existing courses, which are largely dominated by the syllabuses of the examining authorities. With approximately four-fifths of the pupils now leaving secondary schools at school certificate level, the huge gap between examination mathematics and the essential needs of after-school life calls for some fundamental change. The need for a fresh approach to the mathematical curriculum has been ably dealt with by Mr. C. T. Lear Caton in his presidential address to the Midland Branch of the Mathematical Association (*Math. Gaz.*, July 1945), and his advocacy "to replan the mathematics courses in all types of schools to fit in with the new educational structure and to contribute more effectively to the needs of the post-war world" sums up very concisely the case for immediate reform.

In Britain, the logical process of making necessary basic changes in established systems is traditionally slow; but the second great world war has shattered many of those systems so that progressive action is urgently imperative. The late Sir J. J. Thomson ("Recollections and Reflections") tells of a student who only learned to respect mathematics because of its application to billiards! This interesting case typifies the need for emphasizing the outward aspect of the subject and provides the clue to the guiding principle for reform. The problem, however, is far from easy, for it will obviously be dangerous to swing over to the other extreme by rejecting all that has no relation to what Sir Percy Nunn calls "the world of outer realities lying in time and space" ("The Teaching of Algebra"). On the other hand, there is little reason in placing a canopy of alleged difficulty round such a topic as infinite series when they hold the very key to the method of calculating tables, about which most students are so inquisitive. Indeed, the whole trend of any movement towards an intelligent reformation must be directed with much understanding, mature knowledge and an absolutely unbiased outlook.

Quality Control in Business

A SERIES of six articles by Mr. William B. Rice on quality control in business production and administration have been separately reprinted from *Western Industry*, the *Journal of the American Statistical Association* and the *Accounting Review*, and provides a useful introductory account for anyone interested in the application of statistical methods in business. Mr. Rice, who is the director of the Department of Statistics and Reports of the Plomb Tool Company of Los Angeles, writes with first-hand experience of the methods he describes and drives home his points with a wealth of practical illustration. The first four of his articles deal with the control of quality of a manufactured product on fairly familiar lines—an expository presentation which should do much to arouse interest among manufacturers. In the remaining two he extends the technique to business administration and office accounting, showing, for example, how excessive overtime costs in a department of an engineering plant were tracked down and eliminated, and how administrative charges in a business were brought under control. This is quite a recent development of the subject, and provides an interesting illustration of the growth of scientific methods in the most ordinary commercial operations.

The statistical theory required in quality control is comparatively elementary; but the most striking successes have been obtained by introducing it into factory production processes. In some cases the methods amount to little more than a systematic sampling of the product and a graphical presentation of the results; and yet they appear to lead to the tracing of sources of trouble in the manufacturing process with an efficiency which astonishes nobody more than the men who have had years of experience on the job and are naturally inclined to think that they have nothing more to learn about it.

Nutritive Values of War-time Foods

DIETARY surveys of the population which are being carried out by the Ministries of Food and Health have created a demand for food-tables giving, for raw foods, values for proteins, fats and carbohydrates and for the relatively small number of minerals and vitamins most likely to be deficient in human diet. Values for the composition of many foodstuffs consumed in war-time were not available in existing tables, and the differences between the values for war-time and peace-time foods are often very great. The Medical Research Council War Memorandum No. 14 now sets out "Nutritive Values of Wartime Foods" (Tables compiled for the Accessory Food Factors Committee. London: H.M. Stationery Office). Numerous analytical data, published and unpublished, have been considered in selecting the representative values in these tables. Many individuals have been consulted and have provided valuable data and advice. The values, including those for waste, are based for the most part on the results of direct analyses carried out during recent years in Britain. Such values were not always available, particularly for the vitamins, and it was necessary to make a selection from the values in the literature, distinguishing carefully those foods the composition of which had not been affected by the War. The losses during cooking are variable, affecting vitamin C severely, vitamin B_1 to a less extent and vitamin A probably still less. For processed foods, an allowance for loss of vitamins by destruction during cooking has been made in the tables.

Control of Weeds by Spraying

Loss in yield of cereal crops from competition with annual weeds is more serious than is generally realized, and gains of more than 50 per cent can often be expected as a result of correct spraying with a selective weed killer. Advisory Leaflet No. 315, Weed Control in Cereals, issued by the Ministry of Agriculture,

X-Ray Analysis with the Aid of the 'Fly's Eye'

IN a note in *Nature*[1], an example was given of the use of the 'fly's eye' for X-ray analysis. The reflexions of X-rays by planes around a crystal zone correspond in intensity to the optical spectra produced by a cross-grating, the pattern of which is that of the crystal structure projected on a plane perpendicular to the zone. The 'fly's eye' enables such cross-gratings to be made. The spectra they produce can be compared with the observed X-ray reflexions, thus avoiding the labour of calculation, at any rate in the first stages of the usual trial-and-error method of seeking the solution.

The original type of 'fly's eye' was a multiple pinhole camera, the holes being in a square array, forty to the centimetre. Each hole produces an image of a single illuminated object representing the unit of structure. An example of a cross-grating made in this way by Bunn is shown in Fig. 1*a*. It represents phthalocyanine and gave a good correspondence with observation (see *Nature*, *loc. cit.*). It has the disadvantages, however, that the images are diffuse because of the pinhole method and the grain of the photographic plate, and they are unequal in intensity because the minute pinholes are liable to be blocked by specks of dust.

The new type of 'fly's eye' described here gives much better cross-gratings. The pinholes are replaced by small lenses embossed on the surface of a 'Perspex' sheet. These are made by pressing a steel ball at regular intervals on a soft copper block, and casting or pressing 'Perspex' on the block. The actual array used for Fig. 1*b* consisted of lenses 0·5 cm. in focal length, 0·06 cm. in diameter and 0·13 cm. apart. A paper mask punched with corresponding holes cut out all light except that falling on the lenses.

The array of lenses, covering a circular area of 2·5 cm. diameter, with a photographic plate in their focal plane, is exposed to an illuminated ground-glass viewing screen on which black disks are laid representing the atoms in a single unit of pattern. They appear as transparent holes in Fig. 1*b*, which is an enlargement of the negative used as the cross-grating. The greater sharpness and uniformity of the pattern in Fig. 1*b* as compared with Fig. 1*a* is evident. The structure is that of durene[2] projected on (010), and referred to equal axes at right angles.

The cross-grating is mounted between optical flats with cedarwood oil in the interspaces, to reduce optical imperfections of the photographic plate. It is placed before a lens 1 metre in focal length, and the spectra photographed on a plate at the focus. It is convenient to use an eyepiece for viewing them. Fig. 2*a* shows the spectra so produced, the numbers representing the X-ray intensities recorded by Robertson. If allowance is made for the more rapid falling off of X-ray intensities with angle, due to the carbon scattering factor, it will be seen that the correspondence is good. Fig. 2*b* shows the poorer result when the optical flats and cedarwood oil were not used.

The new method has several advantages over the former one. The cross-grating is on a larger scale, hence the grain of the plate is not troublesome. The sharpness of the images should make it possible to represent the atoms as concentric rings so as to simulate the scattering curve of atoms. A series of gratings can quickly be made with different arrangements of the disks on the viewing screen, and it is therefore a rapid trial-and-error method in seeking a first approximation to the structure.

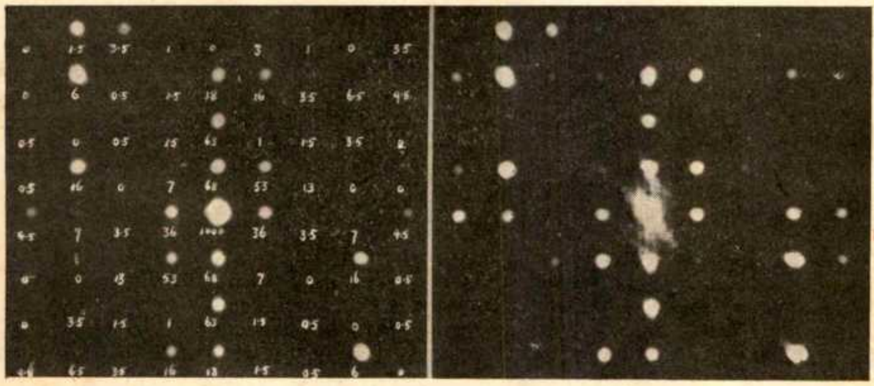
Fig. 1.



(*a*) (*b*)

Fig. 2.

gives much useful information on the subject. Up to the present, sulphuric acid has proved to be the most effective chemical for the purpose, as it kills a wide range of weeds and is quick acting even in dull weather. Its highly corrosive properties, however, make it difficult to handle; so copper chloride and dinitro-ortho-cresol (D.N.O.C.) are suggested as alternatives. Directions for the use of all three substances are given, and comparison made between the concentrations of spray required in each case for the eradication of a number of common weeds. As regards time of spraying, rather more latitude is possible with copper chloride and dinitro-ortho-cresol than with sulphuric acid, which kills weeds only in the seedling stage, but usually the acid has a slight advantage if the weather is cold and dull. Full instructions are given in the use of these spray materials, and any precautions necessary for the protection of the operator or care of equipment clearly mentioned.

West of Scotland Field Studies Council

In 1944 members of the Glasgow and Andersonian Natural History and Microscopical Society, including Dr. Inglis Cameron, carried out preliminary work which resulted in the inauguration in April 1945 of the West of Scotland Field Studies Council. On the Council are representatives of youth organizations, scientific societies, colleges and the University of Glasgow. Prof. Balfour Brown and Prof. C. M. Yonge, who have connexions with similar organizations in the south of Britain, are also on the Council. The Council is mainly, but not exclusively, concerned with the popularization of field studies. Its membership is widely representative, and includes amateur and professional naturalists, educationists, representatives of the Scottish Youth Hostels Association, Boy Scouts, etc. Its constitution provides it with useful powers of co-option. The Council is anxious to get in touch with other organizations of a similar nature, so that some type of co-operation may be established and there may be a free exchange of ideas. It has already set up panels of lecturers and outdoor guides, and is considering the preparation of guide-books to the natural history of the west of Scotland. The chairman is Prof. John Walton; the honorary secretary is Dr. T. Gregory Absalom, Art Galleries and Museum, Kelvingrove, Glasgow, C.3, to whom communications should be addressed.

Durban Museum and Art Gallery

In the annual report for 1943–44 of the Durban Museum and Art Gallery, it is reported that their position as institutions of visual education and æsthetic enjoyment has been well maintained; but reference is made to the now common need among museums in all parts of the world for further and more suitable accommodation. Besides the usual routine work, many public lectures were given in the Museum and Art Gallery throughout the year, and there was much activity in connexion with the school services. The showing of educational films evidently takes a prominent place in these services. In reference to adult education, it is of interest that the South African Minister of Education appointed a committee to inquire into, and report upon, the part played by the Museum and Art Gallery in this realm of their activities. One of the photographic plates in this report depicts an interesting group of carved stone figures entitled "Baya Huba", by Mary Stainbank; this was recently acquired by the Art Gallery.

Biochemical Research Foundation of the Franklin Institute

In Reports of the Biochemical Research Foundation of the Franklin Institute (**7**; 1942–43), stress is laid on the importance of co-ordination of the sciences of physics, chemistry and biology. By this means it is often possible to obtain a comprehensive view of a problem, whereas the isolated methods of the past would only come to an *impasse*. There are more scientific trained personnel in this Institute than in almost any college, and, free from the burden of teaching, all are co-ordinated and organized towards the special end. Direction of research towards certain projects is thus possible, and groups of scientific workers of varied character together with apparatus of unique quality are brought to bear on the elucidation of any problem. An example of this type of group co-operative work is the successful separation by physico-chemical methods followed by biological study of certain surface antigens of the typhoid bacillus having high immunizing powers without any great degree of toxicity.

Announcements

Mr. Roy Innes has been appointed general secretary of the Association of Scientific Workers. Mr. Innes took a degree in mathematics and physics at the University of Manchester in 1937. For a time he was a science teacher, and in 1939 entered the newly formed Operational Research Section attached to Fighter Command, R.A.F. He succeeds Mrs. Reinet Fremlin, who has been with the Association for eight years.

An open meeting to discuss "Social Security for Chemists" has been arranged by the London Section of the British Association of Chemists. It will be held at the Assembly Hall, Royal Empire Society, Northumberland Avenue, at 6.30 p.m. on September 19.

Voks Bulletin No. 6, of the U.S.S.R. Society for Cultural Relations with Foreign Countries, includes a tribute to Mendeléeff, by M. Pervukhim, People's Commissar of the Chemical Industry of the U.S.S.R., in connexion with the seventy-fifth anniversary of the discovery of the periodic law, and an article by the late A. Fersman, of the Academy of Sciences of the U.S.S.R., on the periodic law and its significance for natural science, in which its bearing on geochemistry as well as on cosmic processes and theoretical chemistry generally are considered.

The following appointments have been made in the newly formed Department of Animal Health at the University College of Wales, Aberystwyth: Mr. R. Phillips, formerly senior lecturer in agriculture, to undertake research in animal husbandry and the administration of investigational centres; Dr. W. C. Evans, at present biochemist to the Inoculation Department, St. Mary's Hospital, London, to be special lecturer in biochemistry; Mr. E. Parker Pollard has been seconded by the Cooper Technical Bureau for research in parasitology; Mr. D. N. Fidler, to be research assistant (animal husbandry); Mr. R. A. Evans, at present of Crooke's Laboratories, and Mr. A. W. Davies, formerly of the Dunn Nutritional Laboratory, Cambridge, to be research assistants (biochemistry); Mr. T. R. Thomas, Carmarthen, to be consulting veterinary surgeon.

It is intended to publish elsewhere a more detailed account of the production and use of the gratings.

W. L. BRAGG.

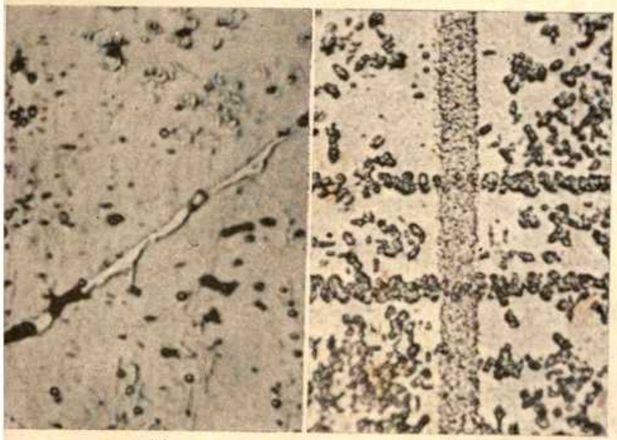
Striated Structure of Age-hardened Alloys

Drs. Guinier and Jacquet[1] have referred to striated structures appearing in polished specimens, etched or unetched, in the earlier stages of the age-hardening of certain alloys and in particular of aluminium-copper and copper-beryllium alloys.

With regard to aluminium-copper alloys, an extensive research into the mechanism of ageing of high-purity 4 per cent copper-aluminium alloy has confirmed the view I put forward in 1940[2], that these 'striations' could be attributed to accelerated ageing resulting from plastic deformation on quenching, and has again led me to the conclusion that they are not a necessary accompaniment of the age-hardening process. The results I have obtained also show that the lattice-strains, set up in the early stages of ageing by the formation of the Guinier-Preston plates, are relieved when the latter attain a critical size by the precipitation of sub-microscopic copper-rich aggregates and sub-microscopic crystallites of the aluminium solid solution stable at the temperature of ageing. The beginning of the 'flat' on time-hardness curves marks the appearance of this process. As ageing proceeds, these copper-rich segregates and crystallites of aluminium become microscopic in size, as shown in Fig. *a*, which is a photomicrograph of the etched structure of high purity 4 per cent copper-aluminium alloy, quenched and aged 80 days at 130° C. White crystallites of aluminium solid solution, stable at 130° C., are seen in the grain boundaries and in the matrix, together with the black areas which are indicative of copper-rich regions.

Furthermore, Wassermann's[3] suggestion that striated structures may be attributed to mechanical twinning resulting from quenching stresses is not confirmed. Fig. *b* is the photomicrograph of part of a large grain of high-purity 4 per cent copper-aluminium alloy, in which several 'striations' were revealed on etching the quenched and aged specimen. The specific etching reagent has developed the crystallites of the aluminium solid solution, stable at the ageing temperature, as referred to above. The 'striations' are composed of many of these crystallites, and it is clear that where the two bands of striæ cross one another, no change in direction occurs. My researches into the relationship between cold-work and age-hardening show that cold-working (strain-hardening) and age-hardening are similar processes, and that when the lattice has been strained to a critical amount, relief occurs by the formation of crystallites of aluminium along the planes of slip, resulting in accelerated ageing. Hence the crystallites shown in Fig. *b* are due to accelerated ageing in strained areas.



(*a*) (*b*)

4 % COPPER-ALUMINIUM (*a*) AGED 80 DAYS, 130° C.; × 2,000; (*b*) AGED 4 HR., 190° C.; × 1,500.

If quenching is very severe, as it was in the case of the specimen mentioned above, 'striations' are formed; it is probable, however, that they are deformation bands of the type found by Barrett and Levenson[4] in compressed aluminium. The spontaneous development of striations in copper-beryllium alloys is, I think, a different phenomenon; rather they are associated with the development of internal strains in the lattice due to the formation of beryllium-rich zones, as postulated by Guinier and Jacquet, and *not* to plastic deformation. The relief of strains set up takes place in these alloys on a macro-scale, that is, with the formation of striations similar in type to Lüder's lines; in the case of copper-aluminium alloys, the relief of strain in the early stages is on a sub-microscopic scale and is not accompanied by 'striations'.

In the near future I hope to publish full details in support of my statements.

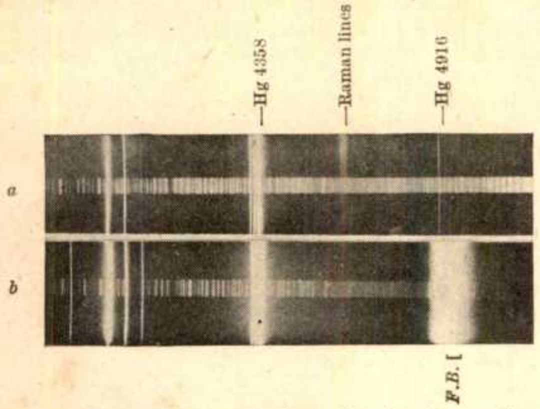
Fluorescence of Dipropyl Ketone at Low Temperatures

IT is well known that fluorescence bands sometimes undergo changes in position and intensity with the change of state and temperature of the substance, and also they sometimes show some structure at low temperatures. Organic substances which do not exhibit any fluorescence at room temperature but show intense fluorescence bands at low temperatures are, however, very rare.

While investigating the Raman spectra of organic substances at low temperatures, we have observed that dipropyl ketone is one such substance. When it is irradiated in the solid state at about −170° C. by light from mercury arcs condensed by thick glass condensers, it yields a feeble Raman spectrum containing also a very intense fluorescence band extending from λ 4880 up to λ 5100, the short wave-length edge of the band being less diffuse than the long wave-length edge. The Raman spectrum of the liquid at room temperature observed under similar conditions does not show any appreciable fluorescence in the visible region, as can be seen from the spectrum reproduced; the spectrogram for the solid at about

$-$ 170° C. is also reproduced. It can be seen that the intensity of the fluorescence band is as large as that of the undisplaced mercury lines, even though a narrow slit was used; the undisplaced mercury lines were due to strong stray diffuse light coming from the irradiated mass of the solid, which was translucent.



It has been observed that the band mentioned above does not appear immediately after the double-walled 'Pyrex' tube containing the liquid is completely immersed in liquid oxygen. This shows that the band is not due to liquid oxygen. The substance freezes at $-$ 32·6° C., but the band does not appear even when the liquid is solidified and the temperature goes down below $-$ 50° C. As the temperature is lowered further, a feeble continuous fluorescence extending from λ 4920 up to about λ 5300 is observed, and when air at atmospheric pressure is allowed to fill up the annular space between the walls of the double-walled container, the temperature of the solid attains a value of about $-$ 170° C. and the intense band shown appears simultaneously. Visual observations show also the presence of a very weak diffuse and broad band at about λ 5200; but owing to the insensitivity of the plate in this region this band has not been recorded on the plate.

The facts mentioned above indicate that change of state of the substance is not responsible for the origin of the band. It is the contraction of the solid at lower temperatures which gives rise to the strong fluorescence. Thus probably this fluorescence of dipropyl ketone furnishes direct evidence of the appearance of fluorescence due to strain in the molecular lattice. The investigations are being pursued.

Hydrogen Bond Linking of Quinol Molecules

CRYSTAL structure examination has shown that quinol molecules may link by hydrogen bonds in a special manner. The compound $SO_2.3C_6H_4(OH)_2$ [1] is found to have a rhombohedral lattice; the corresponding hexagonal unit cell, $a = 16{\cdot}3$, $c = 5{\cdot}8_1$ A., contains nine molecules of quinol and three of sulphur dioxide. From X-ray intensity relationships and absent spectra, the evidence of face development, and the negative results of pyro-electric and piezo-electric tests, the space group should be $R\bar{3}$. For β-quinol, Caspari[2] found a unit cell of very similar dimensions, without a centre of symmetry, and of the possible space groups C^1_3–$C3$ and C^4_3–$R3$ preferred C^1_3–$C3$; a determination of atomic positions was not attempted. We have confirmed the polar character, but from absent spectra find the space group to be C^4_3–$R3$. From the great similarity, after allowance for the sulphur dioxide, between our X-ray data for β-quinol and the sulphur dioxide compound, the two structures must have much in common. As a safeguard, therefore, against erroneous conclusions due to faulty space group suppositions, the structure of the sulphur dioxide compound was developed, without the initial assumption of centrosymmetry, by three-dimensional Patterson and Fourier methods. In the early stages this procedure brought in a symmetry centre, and for the subsequent work the space group was taken as $R\bar{3}$ in accordance with this and the other evidence.

The linking of quinol molecules in this compound may be seen from Figs. 1 and 2. In Fig. 1, circles represent oxygen atoms of the hydroxyl groups linked by hydrogen bonds to form approximately plane hexagons of side 2·7 A. These hexagons are connected as shown through rods which represent the quinol molecules. For clarity the benzene rings have been omitted, and the rod itself coincides with the line joining the two oxygen atoms of one molecule. This gives a set of quinol molecules linked to form an infinite cagework in three dimensions. Although the hexagon is a satisfying hydrogen bond arrangement, having a parallel in the crystals of boric acid[3], and the oxygen to carbon link represented by the direction of the rod is at nearly the tetrahedral angle to the two hydrogen bonds as is commonly the case, the molecular grouping of Fig. 1 is a very ineffective one for space filling. Comparison with the 2·7 A. sides of the hexagons will show a very large central space and, on each face of the roughly rhombohedral framework, gaps which are wide compared with an atomic diameter. These gaps are so large that it is possible to insert a second identical framework. This is displaced vertically half-way between the top and bottom hexagons, and the holes of the structure are such that the two cageworks are able to interpenetrate each other without closer contact than that usual for unlinked atoms. A drawing cannot represent this owing to overlap effects, but the stereoscopic representation of Fig. 2 gives a simple visual demonstration of the relative dispositions of two frameworks each identical with that of Fig. 1, but viewed from a different angle for convenience.

Although the two frameworks now approach to give normal van der Waals distances and there are no gaps

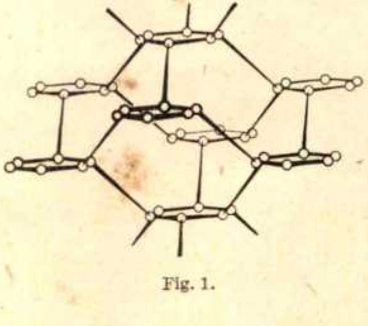

Fig. 1.

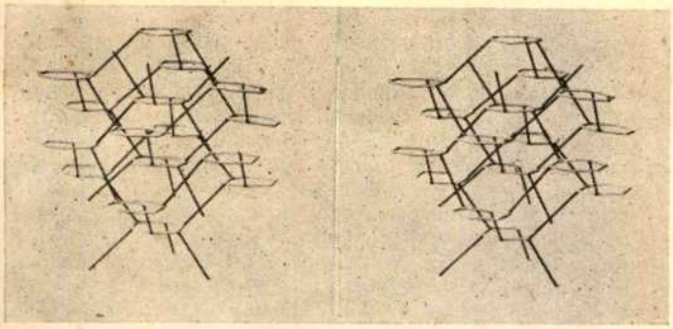

Fig. 2. THE STEREOSCOPIC EFFECT MAY BE OBTAINED BY USE OF A SIMPLE STEREOSCOPE, FOR EXAMPLE, HILGER'S, OR BY HOLDING A CONVEX LENS OF FOCAL LENGTH c. 10 CM. CLOSE TO EACH EYE.

through which a molecule may easily enter or leave, there remain, between the two cageworks, cavities of sufficient size to contain a small molecule at normal unlinked distances from the surrounding atoms. These cavities, which may be seen in Fig. 2, are bounded at top and bottom by the hydrogen bond hexagons of the two different cageworks and at the sides by quinol molecules as a whole. It is in these separate enclosures that the sulphur dioxide, or other molecule in similar compounds, is located.

The detailed structures of the compounds and a discussion of applications of the type of union exemplified will be given elsewhere.

Note added in proof. Our unit cell dimensions, slightly greater than Caspari's, led to further work including a molecular weight determination from unit cell size and density, comparison of X-ray intensities and chemical analyses, all of which show that 'β-quinol' crystallized from methyl alcohol is a compound containing one molecule of methyl alcohol to three of quinol and is thus closely related to the sulphur dioxide compound.

Degree of Association of Water from the Energy of Viscosity and the Work of Cohesion

ON a previous occasion[1], it has been shown that the energy of viscosity equals the work of cohesion for non-associated liquids. For associated liquids the energy of viscosity is greater than the work of cohesion by a definite increment. This increment of energy is the energy of association per bond between two associated molecules. Equating the difference between the energy of viscosity, $E_{\text{visc.}}$, and the work of cohesion, W_c, to the energy of attraction between two interacting dipoles, it is possible to calculate an apparent dipole moment of the molecule, and from the apparent dipole moment one can calculate the degree of association of the substance. Thus it is postulated that for a liquid where all the dipoles take part in association complexes,

$$\frac{E_{\text{visc.}} - W_c}{N} = E(r)_{\text{dipole interaction}} \quad . \quad . \quad (1)$$

where $E(r)_{\text{dipole interaction}}$ is the energy of interaction between two dipoles.

This energy of interaction between two dipoles results from the summation of two effects: (*a*) the attraction between the dipoles[2] (the so-called orientation effect); (*b*) the mutual enhancement of the dipole moments of the molecules by mutual interaction, due to the polarizability of the molecules[3].

Let μ be the dipole moment of the molecules, r the distance between the centres of the dipoles and p the polarizability of the molecules; then for a parallel arrangement of the dipoles:

$$E(r)_{\text{orientation}} = \frac{\mu^2}{r^3};\ E(r)_{\text{polarizability}} = \frac{2.\mu^2.p}{r^6}; \quad . \quad . \quad (2,\ 3)$$

and

$$E(r)_{\text{dipole interaction}} = E(r)_{\text{orientation}} + E(r)_{\text{polarizability}} \quad . \quad (4)$$

From equations (1) to (4) it follows that

$$\mu = \sqrt{\frac{E_{\text{visc.}} - W_c}{N} \cdot \frac{r^3}{1 + 2p/r^3}} \quad . \quad . \quad (5)$$

If all the dipole molecules would form association complexes, then equation (5) would give the true value of the dipole moment. However, the difference between $E_{\text{visc.}}$ and W_c derives only from the fraction of the molecules which take part in the associated complexes. If the liquid is only partially associated, equation (5) will give an apparent dipole moment smaller than the 'true' or experimentally determined moment.

Writing

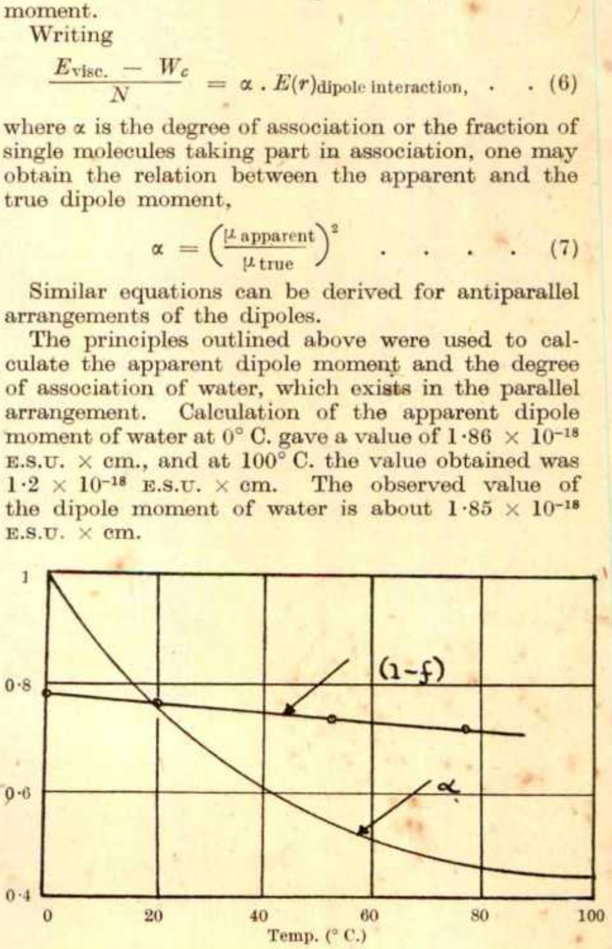
$$\frac{E_{\text{visc.}} - W_c}{N} = \alpha\ .\ E(r)_{\text{dipole interaction}}, \quad . \quad . \quad (6)$$

where α is the degree of association or the fraction of single molecules taking part in association, one may obtain the relation between the apparent and the true dipole moment,

$$\alpha = \left(\frac{\mu_{\text{apparent}}}{\mu_{\text{true}}}\right)^2 \quad . \quad . \quad . \quad . \quad (7)$$

Similar equations can be derived for antiparallel arrangements of the dipoles.

The principles outlined above were used to calculate the apparent dipole moment and the degree of association of water, which exists in the parallel arrangement. Calculation of the apparent dipole moment of water at 0° C. gave a value of $1{\cdot}86 \times 10^{-18}$ E.S.U. × cm., and at 100° C. the value obtained was $1{\cdot}2 \times 10^{-18}$ E.S.U. × cm. The observed value of the dipole moment of water is about $1{\cdot}85 \times 10^{-18}$ E.S.U. × cm.



The degree of association of water was then calculated and the results are shown on the accompanying graph. According to our calculations, near the melting point water is completely associated (that is, every molecule takes part in associated complexes), while at the boiling point only 42 per cent of the molecules behave in this manner. It is interesting to compare the values of α with the fraction of the dipoles, f, which have free rotatory power as given by Bernal and Fowler[4]. The values of $(1 - f)$, the fraction of the dipoles having no free rotatory power, are given graphically.

At present work is in progress to apply these principles to other substances and to the mechanism of viscosity.

The Fitzgerald Contraction as the Origin of our Experience of Time and its Lapse Rate

LET it be assumed that the origin of the sensation of time and the flux of time lies in the Fitzgerald contraction of brain material. If the brain material is carried relatively to 'space' or 'ether' with constant speed, the sensation will be steady in amount, and so the flow of time will seem to be uniform. For all speeds of motion the contraction is a well-known function of the speed, and it is the most simple postulate that the sensation of the lapse-rate of time is altered correspondingly.

Sir James Jeans has advanced the postulate that the brain is responsive to the one-way increase of entropy. This is possible and perhaps plausible in virtue of the magnitude of the individual brain mechanism attached to a centre of brain response; but it must be remembered that entropy flux can only be presumed to be steady as an average. There is no such limitation in the case of the Fitzgerald contraction. Its action is one-way unavoidably.

Using Maxwell's equations in the form

$$\text{Curl } E + \dot{B} = 0 \text{ ; div } B = 0 \text{ ;}$$
$$\text{Curl } H - \dot{D} = 0 \text{ ; div } D = 0 \text{ ;}$$

which characterize Schrödinger's recent treatment[1], that treatment makes clear the possibility of employing Maxwell's electromagnetic theory in the wave mechanics of the present day.

By accepting only data susceptible of ideal or actual demonstration, a possible large and fruitful line of investigation is closed, and we are faced with the complicated picturization of reality as given in terms of relativity and quantum wave mechanics. The existence of ether has been denied and 'space' enthroned instead. As Sir J. J. Thomson, in forming an ideal working model of the proton in ether, asks: Why not call it ether instead of space and get rid of the difficulty? Schrödinger's suggestions repeat the demand with the additional simplification of the explicitly stated quality of Maxwellian.

In this connexion we have to regard afresh the striking announcement given to the International Congress of Physics at Paris in 1900 by Kelvin, at once of his renunciation of the longitudinal component of the electric displacement in wave motion through the ether; of his adoption instead of Maxwell's electromagnetic ether; and of his final adherence to Boscovich's theory of the action of forces, of electric attraction or repulsion as providing a basis for the connexion of matter with ether.

In this way, Kelvin brought to a triumphant conclusion in 1900 his work on wave-theory, matter, and ether, begun in his Baltimore Lectures in 1884, and continued intermittently throughout the intervening years. This was perhaps the greatest investigation made in theoretical physics since Newton wrote. It vindicated the claim that investigators in physics should not be trammelled by the modern arbitrary restriction. The picture of Nature they give may actually lie nearer its heart.

Now, with this claim made prominent, what, more fully, of the picture of Nature presented by Kelvin? Primarily, the Maxwellian ether, having negative compressibility and made stable by atomic support in a material medium built up of these atoms. If a physicist of Kelvin's rank was satisfied with that, it should surely give confidence.

Finally, let this ether be that part of the ether contemplated by Schrödinger[1], corresponding to Maxwell's electromagnetic equations. We need only consider the four dimensions of ether, three mutually perpendicular to each other in our own universe, and one normal to those in the fourth dimension. Regard the ether flux as entering the three-dimensional model, contemplated by Schrödinger, from the fourth dimension, and we can regard the working of the model as due to the energy carried into the model by the etherial current. There is no need to contemplate as existing in reality any higher order of ether dimensions than four. To consider space-time only complicates the picture of reality offered to us.

Bread in Jersey during German Occupation

THROUGH Mr. E. F. Mitchell, president-elect of the National Association of Master Bakers, Caterers and Confectioners, we received a sample of bread made in Jersey during the German occupation. The analytical data we obtained on this sample will probably be of interest to many.

The bread was naturally stale and dry, so that it is possible, in view of the moisture content (10·9 per cent), to compare the figures obtained directly with those of flour or meal. The bread had the disadvantage of being very dark and unappetizing, while it did not have the advantage of a high vitamin B_1 content usually associated with dark and long-extraction bread. Actually, the vitamin B_1 figure is no higher than that of the present fairly good coloured 80 per cent flour, which has about 0·80 I.U./gm. The riboflavin is also not especially high; but the nicotinic acid content is substantially higher than that of present-day flour in Great Britain.

It will be observed that the bread has a very high fibre content, due to the presence of some very coarse fibrous material. We have examined a portion of this material sieved out from the flour. It is not of the nature of bran and appears to be just coarse extraneous fibrous material. We are informed that 3–4 per cent of such material can be easily sieved out of the flour without removal of bran. It had a fibre content of more than 16 per cent and a vitamin B_1 content of only 1·0 I.U./gm. The presence of this material naturally reduces the digestibility of the bread.

	Bread received from Jersey %	Present-day 80% flour %
Moisture	10·88	13·50
Protein (N × 5·7)	8·27	11·40
Ash	2·71*	0·75
Oil (by hydrolysis)	0·81	1·80
Fibre	2·87	0·20
Carbohydrates and undetermined matters (by difference)	74·96	72·35
	100·60	100·00

* This contains 1·69 per cent salt

	Bread received from Jersey.	Present-day 80% flour
Vitamins—		
B_1	0·77 I.U./gm	0·80 I.U./gm.
Riboflavin	0·82 μgm./gm.	0·60 μgm./gm.
Nicotinic acid	36·0 μgm./gm.	16·0 μgm./gm.

Progressive Clines

THE geographical regularities of variation, including the well-known examples subsumed under Bergmann's and Sloger's rules, have been receiving much attention from recent writers on evolutionary subjects, under the general head of 'clines'. However, the type of cline involving increasing specialization in a given geographical direction, although first described more than forty years ago, seems to have been entirely neglected in these discussions.

In 1902, Leche[1] in discussing the hedgehogs (*Erinaceus* s.l.) pointed out that within three of the groups into which he divided them, the geographical representatives showed an increasing specialization as one proceeds from North India towards North Africa. (He was apparently mistaken as to the affinities of form, but the correction only makes the case still more convincing[2].)

As a result of careful studies of the horseshoe bats (*Rhinolophus*), Knud Andersen[3,4] arrived at similar conclusions. The Ethiopian forms are less primitive than their relatives farther east, notably in the following characters: (1) the reduction of certain premolars (a general tendency in bats); (2) specializations of wing-structure (here his conclusions were confirmed by Revilliod[5]); and (3) detailed structure of the nose-leaves. Disregarding the last point, the value of which as an indication of evolutionary level may be questioned, we can still say that wherever such differences are demonstrable, forms from Africa and the Western Palæarctic are more specialized than their nearest relatives in the Oriental region. In this genus, forms from the western and eastern areas are seldom conspecific, and there is often considerable geographical overlap. Evidently, barriers to intercrossing are very easily developed even between closely related groups in *Rhinolophus*, thus accounting for the astonishing number of species in the genus.

The most important of a number of examples cited by Leche in a later paper[6] concerns the porcupines of the genus *Hystrix*. Thus the enlargement of the nasal region (which is already marked in *H. brachyura* from the Malayan region in comparison with more primitive genera) is much more extreme in the Mediterranean *H. cristata*, where the nasals cover more than half the dorsal surface of the skull, and (together with the frontals) are enlarged vertically by air sinuses. Indeed, the erection of a separate genus *Acanthion* for *H. cristata* would be quite justified were it not for the almost complete chain of intervening forms in India and Western Asia. There is no geographical overlapping between these, and it may be possible to consider all of them as forms of one polytypic species or super species.

For character-gredients of this sort, which unlike the usual ones clearly pertain to different evolutionary levels, I propose the term progressive clines, in accordance with the cline terminology introduced by Huxley[7].

Whereas Leche and Andersen both considered this phenomenon as migration in the direction of the more advanced forms (that is, from east to west), I have proposed an alternative explanation[8], namely, the far greater climatic changes during the Tertiary in the western part of the Old World, as opposed to the relatively stable conditions in the Far East. Further, owing to the Atlantic acting as an outlet to the drift ice during the Glacial Period[9], the land masses bordering on that ocean have also been subject to a maximum of climatic change during the Pleistocene. In regard to man, Hazayyin[10] has emphasized the importance of these changes in stimulating the evolution of Palæolithic cultures, which have an important centre of dispersal in the Saharan region. In other organisms the influence of changing conditions upon the rate of evolution is generally recognized, and has been confirmed by modern theory. Furthermore, division of a species into several more or less isolated populations is also favoured by severe conditions, and this tends to produce the same effect[11].

A cline such as that found in *Hystrix* might be termed an orthogenetic series, but that the occurrence of the most advanced forms in the region where external factors known to favour rapidity of evolution are most pronounced makes it unnecessary to assume the operation of orthogenesis in the sense of a hypothetical immanent force or agency.

A final decision as to whether these clines have anything to do with migration or not is possible only from very full palæontological data. The few cases where we have some information of this sort are not favourable to the migration theory.

The red deer of Europe is generally believed to be descended from the closely related Tibet stags, with more primitive antlers; Central Asia is therefore regarded as the original home of the group. Recently, Beninde[12] described a deer from the Lower Pleistocene of Mosbach, *Cervus acoronatus*, which is apparently directly ancestral to the recent European species, and almost identical with one of the Tibet stags, *C. macneilli*, the latter being slightly more advanced[13]. This seems to prove that the higher specialization of *C. elaphus* was not correlated with a westward migration from an eastern origin; it may just as well have had a western cradle, whence, as *C. acoronatus*, it spread eastwards. It is significant that the region adjacent to the eastern border of Tibet, where *C. macneilli* occurs, is an important refuge for primitive forms (for example, *Uropsilus*, the giant panda).

Secondly, the European badger (*Meles m. meles*) may be considered more advanced (in the excessive broadening of the upper molars) than the races of Asia Minor (*M. m. ponticus*[14]) and Persia (*M. m. canescens*[15]). But even as recently as the earliest Neolithic of Denmark, some eight thousand years ago, the badgers of this country were more primitive in this respect, approaching the Asiatic forms[16].

South African Onychophora

ATTENTION has been directed in the Research Items in *Nature* of May 26 to a paper by Holliday[1], on the habits of South African Onychophora, *Opisthopatus cinctipes* and *Peripatopsis Moseleyi*, from Natal. Both this work and an earlier publication by the same author[2] have dispensed with the custom of reference to published literature.

A number of subjects are dealt with, but in nearly every case the facts described have long been known and in recent years much research has been directed to them in Britain. The note in *Nature* directs attention to Holliday's observations on the season of birth of *P. Moseleyi*, and to the number of young born per year; to the new-born young eating their first moult; and to the covering of food by saliva and the probability of at least partial liquefaction of the food before ingestion.

The months of birth and the number of young of *P. Moseleyi* was published by Purcell in 1900 for Natal[3], and data for other localities by Manton[4] in 1938. The fact that *Peripatus* usually eats its moulted integument has been established for many years (Steel, 1896[5], and others). A very much more detailed account of the feeding mechanism, use of saliva, the ingestion of both solid and liquid food, the nature and mode of action of the digestive enzymes of the salivary and intestinal juice, etc., has been published by Heatley[6], and Manton and Heatley[7]. Concerning the drinking by *Peripatus*, Holliday makes no reference to the much fuller treatment of the control of water-loss and the occurrence of drinking by Manton and Heatley[7], and Manton and Ramsay[8].

Work on the South African Onychophora has been going on in Britain for the past twelve years. Four species were brought to England alive in 1933 and two species lived in the Zoological Laboratory, Cambridge, for four years after removal from their native haunts.

Use of Stereographic Projection for Statistical Problems

MR. NAYLOR's recent article[1] on an approximate method for estimating multiple correlation should direct attention to the many possible uses of projection methods in statistical work. The proof that he quotes from my lengthier and more accurate procedure referred primarily to the substitution of a stereographic projection in demonstrating Pearson's equations for correcting for selection[2]: the special problem of partial correlation was treated as an extreme case of selection. (There is incidentally an unnoticed error in Pearson's own diagrams; his placing of D and G relative to E and F violates the conditions of consistency which must obtain for correlations between three real variables.)

I should, however, point out that the formulæ that follow from my proof differ somewhat from those reached by Mr. Naylor. He assumes that it is only "*beyond the first combination*" (his italics) that "the partial regressions are not quite equal to the partial correlations". But even partial regressions of the first order cannot be identified with the corresponding partial correlations. Hence his equation for the proportionate weighting of A and B should read.

$$\frac{\text{Weighting for } A}{\text{Weighting for } B} = \frac{b_{CA.B}}{b_{CB.A}} = \frac{\cos B \sin CB}{\cos A \sin CA} = \frac{\sin PB}{\sin AB}$$

Thus, the weights should be proportional, not to the angles at the base (as he states), but to the segments into which the base AB is divided.

From the equation in this form it is quite possible to build up *exact* expressions for multiple correlations of a higher order. As his note implies, I have found both globular and stereographic projections a useful aid for illustrating these formulæ; but for practical computation I am doubtful if either the exact or the approximate procedures are really superior to the more familiar devices in common use.

For laboratory work we have used printed stereographic nets (obtainable from T. Murby and Co., now Allen and Unwin, Ltd.) and a boxwood stereographic scale (from C. F. Casella and Co., Ltd.). But for correlational studies (for example, rotation of factors) it would be helpful if the nets and scales could be marked in terms of cosines rather than of angles.

RELATION OF THE GONADAL HORMONES TO CERTAIN DERMATOSES*

By Dr. GEORGES GARNIER
Paris

IN this article those dermatoses arising from female gonadal hormone disturbances are described. It goes without saying that other hormones may be involved in like cases, and that hormonal dysfunction can also be a factor in dermatoses in men. The description is limited to women because in them the origin of hormonal dermatoses is often demonstrated by accompanying genital dysfunction due to disturbance of hormonal balance or to hormone deficiency, which can be corrected by synthetic hormone therapy to give results which are striking enough to confirm the diagnosis.

Varied though they are, the dermatoses considered here represent only a few of the aspects of the bearing of the hormones on the skin, which, as Novak has said, "is directly and precisely influenced, as is no other tissue to the same extent, by modifications in the genital system".

Eczema. This is a dermatosis in which a gonadal hormone factor is often demonstrable. I have already related to the Société de Dermatologie[1] two observations which demonstrated, first, the importance of hormonal imbalance in certain eczemas, and secondly, the bearing of this factor in the treatment of these diseases which often resist the ordinary remedies but are cured by injections of the requisite hormone. Both cases were in young women who gave long histories (twelve years in one, six in the other) of chronic eczema of the backs of the hands and wrists. Although they both had shown phases of improvement alternating with aggravation, their skin lesions had never completely disappeared except during pregnancy. In both cases the eczema had cleared up at the beginning of pregnancy only to reappear again a short time after term. Both patients had normal menstrual cycles and gave histories of premenstrual aggravation and post-menstrual attenuation of the disease. Although these cases were clinically identical, one was cured with œstrone and the other with progesterone. Basically, however, the same mechanism was involved in both cases, namely, a disturbance of balance between the hormones of the follicle and corpus luteum, and restoration of balance produced a cure.

In other cases the cause is a hormonal deficiency rather than an imbalance, as in the case of eczema due to a natural or artificial (surgical) menopause which can be cured by injections of œstrone.

The male hormone can also be used as an anti-œstrogen in the treatment of eczema and other dermatoses. Lafitte and Huret[2], and Lortat-Jacob[3], have had good results from the use of testosterone in certain eczemas of women who presented signs of œstrogenic over-activity.

Psoriasis. The chronicity, resistance to treatment and frequent relapses of psoriasis are well known. The use of hormones has figured among the researches made to find an efficacious treatment.

As far back as 1923 Spilmann, Parisot and Simonin[4] published an observation showing the possibilities in this idea. Their case was a woman who had twice seen her psoriasis disappear completely during pregnancy. Spilmann and his collaborators collected blood from her during the second pregnancy, and when the psoriasis returned three months later, they were able to cure it by injections of the patient's serum which had been kept in a refrigerator. They had, in effect, applied indirect hormonal therapy, and Spilmann, in a later article, suggested that the active principle had been the luteal hormone.

There are some cases of psoriasis which appear at puberty, and others which follow the menopause. It seems reasonable, in such cases at least, to investigate the possibility of a hormonal deficiency or imbalance.

Acne. This is a dermatosis which is obviously related to sexual development. It is never seen before puberty and its connexion with genital dysfunction is well known.

In juvenile acne I have seen good results follow the use of gonadotropic hormones.

The same is not the case in the acne of middle-aged women or of the menopause, when a direct action of the gonadal hormones can be demonstrated. Then it is sometimes a question of an acne of the rosacea type with small papulo-pustules seeded among varicosities of the cheeks and nose (relapsing miliary acne of Brocq). Often these papulo-pustular lesions are localized on the chin where some become indurated and evolve slowly. This localization of acne on the chin in women was known to the dermatologists of old as indicating ovarian dysfunction. In other cases of this type acne with large indurated elements is associated with rosacea. These two forms are frequently seen in women approaching the menopause, or in castrates. Injections of anti-œstrogenic hormones seem to give the best results.

Jausion, who attaches much importance to the role of staphylococcus albus in acne, has shown that this organism grows well on media containing hormones, and states that it grows best in sebum the composition of which resembles that of the sexual sterones.

Herpes simplex. The recurrent type of herpes in women often appears at the time of menstruation. It is probable that hormonal imbalance favours the appearance of this disease which is directly caused by a filterable virus. In most sufferers from recurrent herpes related to menstruation the lesions are trivial, and patients are seldom found who feel it necessary to submit to hormonal treatment.

Pruritus Vulvæ. Rebellious to treatment, long-continued and sometimes so intense as to produce obsession or even suicide, vulval or ano-vulval pruritus occurs at different stages in the sexual history: during the active phase and also at the menopause.

Many German authors (Seitz, Kaufmann, Rust, etc.) have described good results from the use of œstrogenic hormones in the treatment of this condition at the menopause, and I can confirm this in a large number of cases. On the other hand, I have never had the success claimed by these authors by using ointments containing œstrone.

Unlike the other dermatoses already described,

---

* First published in *La Presse Médicale*, June 30, 1942. Translated by Dr. James Marshall.

in pruritus there is almost always a deficiency of œstrone and by replacement therapy cures are obtained which are the more striking in stubborn cases of long standing and accompanied by breakdown in general health.

Lichenification. There have been described cases of circumscribed lichenification (névrodermites) of hormonal origin. In the cases I have observed hormone therapy has produced at best only an improvement in the condition. I have, however, had one case of diffuse lichenification of the thighs in which progesterone caused a very marked improvement[5].

Relapsing Erythema Multiforme. This is a rare type of hormonal dermatosis corresponding to the 'dysmenorrhœic dermatitis' of the Germans, of which I have elsewhere recorded a case[6].

The dermatoses described above are those in which I have been able to define a relationship to the gonadal hormones. There exist others, no doubt, and Desaux[7] has collected a series of cutaneous reactions which he ascribes to hyperœstrinism.

What, then, are the requirements for postulating a hormonal basis in a case of this type? Most important are a history and clinical findings of associated genital dysfunction. With many others I believe that estimation of urinary and blood hormone levels and biopsy of the endometrium are of doubtful value in diagnosis.

The best approach is from the clinical angle. One must discover by careful questioning symptoms of genital functional disturbance which the patient is unlikely to volunteer in connexion with the dermatosis which caused her to seek attention. Any relation between evolution of the lesions and the menstrual cycle must be discovered, for example, premenstrual or intermenstrual exacerbations, or regressions at these times; disappearance of lesions during pregnancy. A detailed menstrual history is essential. One must search for evidence of the clinical syndrome of hyperœstrinism described by the gynæcologists and which, according to Séguy, is characterized by (*a*) intense and painful mammary congestion; (*b*) intermenstrual pain localized in one or both ovaries, which may become palpably enlarged; (*c*) a clear cervical secretion increased in amount and duration over the normal; and (*d*) intermenstrual metrorrhagia. In these cases the periods are usually painful and copious, with clots of blood and mucus, and are spaced every 21 days or even less. In other cases, on the contrary, there is a marked diminution in the menstrual flow, going on at worst to the hyperhormonal amenorrhœa of Zondek.

Unfortunately it is impossible precisely to tabulate the dermatoses with corresponding hormonal deficiencies, excesses or imbalances. There remains, however, therapeutic test: a cure resulting from the injection of a given hormone is good evidence of relationship. Empiricism still has a large part to play in the field of hormonal dermatoses.

Conduct of treatment. It is impossible to lay down hard and fast rules, but certain general principles must be remembered: (1) More dermatoses are related to hyperœstrinism than to a deficiency (relative or absolute) of œstrone. (2) The anti-œstrogens (progesterone, testosterone) are more easily regulated than the œstrogens, the effects of which are sometimes paradoxical or unexpected. (3) While œstrone is a very active substance, progesterone and testosterone are feebly acting anti-œstrogens. In other words, one must use the latter substances in much larger doses than the former.

It is to be noted also that, in certain cases, a dermatosis which has once yielded to, let us say, progesterone can later become resistant to this hormone, but can be alleviated by œstrone. Such necessary therapeutic changes are explained by postulating an alteration in the state of hormonal imbalance. Similar states have been noted by Chiray and his collaborators in certain asthmas of hormonal origin.

Finally, if one wishes to attempt a rapid treatment, which will at the same time establish the diagnosis, one must administer the chosen synthetic hormone by injection, and leave aside oral treatment, in the early stages at least.

The following scheme can be used as a practical guide.

1. *Dermatosis with intermenstrual exacerbations.* (*a*) With evidence of hyperœstrinism: Use testosterone as an anti-œstrogen during the first ten days of the cycle, in doses of 10 mgm., every other day for four or five injections. (*b*) With no evidence of hyperœstrinism: Use moderate doses of œstrone, for example, 3–5 injections of 1 mgm. during the eighth to fifteenth days of the cycle. Beware of high dosage.

2. *Dermatosis with premenstrual exacerbations.* (*a*) Hyperœstrinism is usually the cause: prescribe 3–5 injections each of 10 mgm. of progesterone over the nineteenth to twenty-sixth days of the cycle. (*b*) Excess of the luteal hormone is sometimes present, and may be absolute, or relative, due to œstrone deficiency in the latter half of the cycle. It is in such cases that anti-œstrogens have a paradoxical effect and provoke a premenstrual mammary swelling. Œstrone should be used in relatively large doses, for example, 15 mgm. in three injections over the last eight days of the cycle.

3. *At the menopause.* (*a*) Natural menopause: Use œstrone, at first in small doses (1 mgm. per injection), and progressively raise the dose to reach finally a total of from 10 to 20 mgm. per month, depending on the symptoms and on the effect obtained. If œstrone is badly supported (in women with menopausal hyperœstrinism), change to testosterone giving three 10 mgm. injections per week, every other week. Some cases may be found to react better to the acetate of testosterone than to the propionate. The dosage is the same for both. (*b*) Artificial menopause (surgical or X-ray). In these cases vaso-motor symptoms (flushes, palpitations) and recrudescences of extra-genital disorders conform to a menstrual rhythm. Progesterone should be given by injection to a total dosage of 30 to 40 mgm. per month, during the fortnight preceding the appearance of each menstrual syndrome.

In the last two cases (3(*a*) and (*b*)), treatment must be long continued as it is a true replacement therapy.

PRACTICE OF MEDICINE IN THE UNITED STATES

IN January, 1943, the Council of the New York Academy of Medicine appointed a Committee on Medicine and the Changing Order, which was charged with the study of the economic and social changes which are now taking place or are likely to occur in the future, with the question of how these changes may affect medicine and how the best possible medical care may be made available to the largest number of people at the lowest possible cost. This Committee, composed of representatives of the physicians, dentists and nurses and of laymen belonging to industry and various professions, has issued an interim report (2 East 103rd St., New York, 1945). A final report is expected early in 1946.

During its twenty-two months of activity, the Committee held weekly conferences at which it was addressed by experts. The list of speakers shows that a wide field was covered, for economists, historians, publicists, bankers, industrialists and representatives of labour were among those invited. Other weekly conferences studied medical education, hospital problems, rural and industrial medicine, public health and problems of dentistry and nursing. Monographs on major current socio-medical problems were planned to treat contemporary medicine in all its aspects, and some of these are well on the way towards completion; some short treatises have already been published.

Defining its approach to its problems, the Committee states that medicine carries definite moral and social responsibilities. Modern medical problems have been accentuated by recent economic and social dislocations and have been long in the making. Complicated and costly as its administrative structure now is, medicine has its own history and has continuously tried to improve its science and practice. It has largely depended upon benevolence and charity; this dependence has benefited it, but has created many of its present difficulties. Medicine obviously cannot, without great harm, allow its progress to be governed by profit and loss, and it cannot compromise with quality. There is a widespread demand for good medical care which costs as little as possible, so that medicine cannot continue to work as it has done. If the quality of medicine is to be maintained, medical education and research are basic problems, and laymen must understand what medical education involves. The present curriculum needs revision. Its duration is ever increasing, so that from seven to nine years are spent in training and often several more years in specialized study, so that the medical man begins practice at an advanced age with a large capital investment and a relatively short time in which to recover it. These problems are more important than they appear, and efforts must be made to enable the medical practitioner to become productive earlier without adversely affecting his training. The rapidity of scientific development imposes an increased need for post-graduate education and refresher courses, and this need will increase in the future.

The quality of medical practice is also largely dependent upon public understanding and demand, so that people cannot obtain the full advantages of modern medicine without the intelligent and informed co-operation of the public. Hospitals present major problems. They not only treat the sick, but have also essential educational functions, and any changes made in hospital organization involve numerous factors. The medical man, moreover, nowadays does more than treat the sick; he may look after those who are well, or serve schools, industry, insurance companies, public health and so on; all these activities need planning according to possible future developments. Preventive medicine must also be carefully planned. The economic problems of medicine are complex, but real economy in medical care comes from the quality and competence of the treatment rather than from expenditure upon illness. It is therefore likely that better treatment, even though it costs more, will be the cheaper in the long run. Fewer illnesses rather than lower fees may prove to be the solution.

Current efforts to cure human ills by massive doses of social legislation are full of great dangers, the greatest being the fact that laudable ends will be betrayed by incompetent means used to gain them. Social legislation has, in itself, no power; it must have practical ends and means. Based upon wishful thinking, it can be harmful. We need precise definition of the factors involved and workable proposals which will effect progress. Experiments in various forms of medical care must obviously be undertaken before legislation is attempted.

With all these principles and attitudes of mind, somewhat nebulous though they are, many British medical men will agree. Most of them are, indeed, reflected in recent British plans for the reform of medical education which have been noticed in these columns (see, for example, the report of the Goodenough Committee on Medical Schools and the report of the Committee of the Royal College of Physicians of London, *Nature*, **154**, 315 and 322; 1944). Everywhere in the world the problems confronting this Committee in the United States are demanding attention. It is good to know that most of those who are dealing with them are agreed that, in the future, medical care must be the best that is possible, and at the lowest cost; and that, above all, the freedom of the medical man to act and of the patient to consult whom he likes must be preserved.

OCEANOGRAPHICAL RESULTS OF THE LAST VOYAGE OF THE U.S. NON-MAGNETIC SHIP *CARNEGIE*

THE Carnegie Institution of Washington is issuing a series of reports on the scientific results of the last voyage of the *Carnegie*, and has recently published the first two of the series to deal with physical and chemical oceanography[1]. The voyage was started in May 1928, and was brought to a tragic end after 18 months, when the vessel was destroyed by fire. A general account of the voyage was published by the ship's surgeon in 1932 [2]. One cruise was made in the North Atlantic Ocean, and extensive voyages in the Pacific Ocean, crossing most areas north of 40° S. in the east, and 10° N. in the west.

The publication of both reports has been long delayed. Dr. Sverdrup's chapters on the North Atlantic and Pacific Oceans were written in 1931, and although some revision has been possible, it is not sufficient to take all subsequent work into consideration. The other chapters appear to date from about 1935. While regretting this delay, oceanographers will acknowledge the readiness with which the data have been made available in manuscript form at any time since 1931.

A large section of the physical report deals with the accuracy of the methods of observation. A deep-sea thermometer is suspended fairly rigidly in a stout sealed glass tube which protects it from the effect of pressure. The reading is obtained by arranging to break the mercury thread by making the thermometer turn over in a frame at the required depth. Minor corrections have to be applied, but an analysis of the *Carnegie* measurements indicates that the error in the final reading of a single thermometer was usually considerably less than ±0·045°. By using a pair of thermometers at each depth, the accuracy was increased.

The depth of the observation cannot be assumed to be the same as the length of wire used in lowering the instruments, because surface drift, and possibly undercurrents, make the wire take an appreciable angle from the vertical. The discrepancy is measured by the comparison of readings of two thermometers, one protected against pressure, and the other unprotected and calibrated to show the effect of pressure. A comparison of such measurements with the wire-lengths when the wire was more or less vertical indicated that the thermometer depth measurement was usually reliable to within 1 per cent at 1,000 metres and 0·5 per cent at 5,000 metres. Tables and graphs are given for correcting thermometer readings; but it is believed that they will not be found so generally useful as those by Geissler (1931)[3] and Schumacher (1935)[4], not mentioned in the report.

The *Carnegie* wire soundings were also checked by thermometric depth measurements. Whenever possible the ratio of thermometric depth to length of wire paid out was plotted against the measured angle of the wire at the surface, and the points fall fairly closely about a curve. The depth factor taken from this curve is 0·99 for an angle of 10°, and 0·90 for an angle of 60°. The factors would not necessarily be the same for a different vessel, or one differently manœuvred. The weak point of the *Carnegie* echo-sounder was its timing device, and it has been found necessary to correct the soundings by factors based on the comparison of wire soundings and echo-soundings when they were made close together. When the Fessenden oscillator failed, they used an improvised shot-gun, fired a foot or two below the surface, and made allowance for the greater initial velocity of sound from such an explosive source. It is worth noting that the ultimate standard for the depth measurements was the calibration of the unprotected thermometers, shown to be fairly reliable by the measurements on wires that were nearly vertical.

The analyses of the salinity of sea water were made by measuring the electrical conductivity of samples at carefully controlled temperature. It was a substitution method using water of known salinity. The errors in the determinations proved to be greater than those expected from the titration with silver nitrate, and the electrical method is not likely to replace titration in general use. Minor deviations from the controlled temperature are probably the chief source of error, and they are difficult to avoid.

The second part of the report deals with the information which has been gained from the measurements. One of the most interesting features is a wealth of new information about the deep-water layers in the Pacific Ocean. The measurements confirm that no highly saline water sinks from the surface into the deep layer, and the highest salinities in the deep water are found near the bottom where water of Atlantic and Indian Ocean origin creeps slowly northwards from the Southern Ocean. Compared with the deep-water circulation in the Atlantic Ocean, the Pacific deep-water movements are very sluggish.

The measurements of oxygen, phosphate, silicate and *p*H, described in the report on chemical results, are in close agreement with the conclusions based on temperature and salinity. The concentrations of phosphate and silicate in the deep water are unusually high, and the oxygen contents and *p*H values unusually low, all indicating that the deep water is long removed from the photosynthetic activity of the surface layer, and that there has been time for an abnormal increase in the products of oxidation and decomposition of organic material.

G. E. R. DEACON.

THATCH GRASS

IMPERATA cylindrica (L.) Beauv., which is a widespread grass of the tropics and sub-tropics, thrives on abandoned or poorly cultivated land. Although it may provide fodder suitable for very primitive types of agriculture, it is undoubtedly a troublesome weed which as the result of present upheavals is likely to become even more of a problem than in the past. For this reason a recent publication solely concerned with this species is particularly appropriate*. The booklet, in which five authors collaborate to cull the available literature, is of considerable interest not merely to the agriculturist but also to everyone at all interested in the grasses.

At the beginning is a chapter by C. E. Hubbard on the taxonomy of the species and its five varieties. His lucid explanation of the synonymy and the position with regard to varieties make delightfully smooth reading of an aspect which must have been difficult both to straighten out and to express so clearly. He admits five varieties, of which *major* (Nees) C.E.H. is the most widespread, being found in South-east Africa and Ceylon as well as throughout India, Malaya, Indo-China, the western Pacific Islands and Australia. The variety *africana* (Anderss) C.E.H. occupies a region in Africa south of the tropic of Cancer; var. *europaea* (Anderss) Asch. & Graeb. is confined to an area round the Mediterranean and eastwards across a strip south of the Caspian to Afghanistan; var. *latifolia* (Hook. f.) C.E.H. occurs only in North India, and var. *condensata* (Steud.) Hack. ex Stuckert is a native of Chile.

---

* *Imperata cylindrica*: Taxonomy, Distribution, Economic Significance and Control. Imperial Agric. Bur. Joint Pub. No. 7. Pp. 63. (Imp. Forestry Bureau, Oxford, and Imp. Bureau of Pastures, Aberystwyth.) 2*s*. 6*d*.

Imperata cylindrica ($S=20$) belongs to the tribe *Andropogoneæ*, and Janaki-Ammal has succeeded in obtaining fertile hybrids with *Saccharum*, using, for the ovule parent, plants of the clone P.O.J. 2725 ($S=106$), which itself is derived from the cross *S. officinarum* ($S=80$) × *S. spontaneum* ($S=112$) backcrossed twice with *S. officinarum*.

Unfortunately, the section on the anatomy of *Imperata* falls short of the level of the rest of the work. As it is difficult to convey much information by description alone, there would have been a considerable gain if only a single plate of figures redrawn or copied from the literature could have been substituted for part of the text. Mere descriptions are very inadequate, especially when in a compilation of this sort there seems a tendency to quote authorities just because they have made a statement, regardless of how absurd it may be. For example, what use is there in quoting Duval-Jouve (1875) as saying that round the bundle "There is an inner ring of cells without chloroplasts, the colouring matter being diffused throughout the cell", suggesting that the chlorophyll is either dissolved in the vacuoles or diffused through the cytoplasm? Again, merely saying that in var. *major* "Each vascular bundle of the first order is surrounded with a two-layered bundle sheath, the inner sclerotic, the outer thin walled" might suggest to the uninitiated that *Imperata* should belong to the Pooideæ: a few simple drawings, possibly from Vickery, would have been much more useful than any description.

Although *Imperata* is able to withstand great variation in temperature and will grow up to 2,000 m., and only extreme aridity will prevent it from growing in areas otherwise suitable, it is essentially a tropical or sub-tropical plant. It is light-loving and rapidly colonizes cleared ground or abandoned plantations, spreading profusely by 'seeds' and rhizomes which grow out vigorously from the short basal internodes of the aerial shoots. Its ability to regenerate quickly after firing is one of the factors which make it a menace where primitive shifting cultivation is practised.

Although there are reports of *Imperata* being useful as a nurse crop, it is probably never the best plant for the purpose and is often very harmful later. Again, even if cut continually to encourage a more palatable growth, the general opinion is that it is not a good fodder plant and could probably always be replaced by a better species. (In the chapter on grazing value, an improvement would have been made by stating in Tables 3–5 which are as percentages of dry weight and which as wet weight, and perhaps also, to have included dry-weight percentages in Table 4 for easy comparison with the others.)

After reading the chapters recording the black marks against the species, it is somewhat of a relief to learn that it is apparently the thatch plant *par excellence* and is often cultivated carefully for this purpose alone. No doubt this will lead to a struggle between the various interests in the future.

Its suitability for paper-making is negligible owing to (1) the difficulty of obtaining a product of good colour without excessive bleaching treatment, (2) the short fibre-length, and (3) the impossibility of obtaining sufficiently large and constant supplies of a uniform quality within the economic radius of a mill.

With regard to control, mechanical methods such as ploughing and hoeing are effective especially if persistently employed; but perhaps the line which may be most usefully followed is the exploitation of the plant's intolerance of shade, either by encouraging re-afforestation or by sowing smother crops.

Except for the bibliography, a five-page list of common names in various languages and dialects completes this pleasing little work. If this could be the first of a number of booklets of this type, the others would certainly be at least as welcome, especially at the low price of half-a-crown.

B. C. Sharman.

THE IMPERIAL CANCER RESEARCH FUND

THE forty-second annual report of the Imperial Cancer Research Fund[*] includes an account of progress made in scientific work in the laboratories at Mill Hill.

Mr. H. G. Crabtree has continued his investigations on the effect of substances which retard the carcinogenic action of 3:4-benzpyrene and 1:2:5:6-dibenzanthracene painted on the skin of mice. Bromobenzene and unsaturated dibasic acids, which readily combine with sulphydryl groups, are able to neutralize carcinogenic action. On the other hand, aldehydes, which form unstable derivatives with sulphydryl compounds, have only a slight inhibitory action on carcinogenesis. Another aspect of carcinogenesis, namely, the stimulating effect of wound healing, has been studied by Dr. D. B. Pullinger. She finds that multiple injuries followed by healing may double the incidence of tumours caused by painting with carcinogens. The effect is greatest when the more potent agents are used; with weak or intermediate carcinogens the effect is negligible. The more active carcinogens are presumably able to overcome resistance to the neoplastic change.

The relation of mammary cancer and the milk factor or mammary tumour inciter, present in the tissue of mice belonging to strains susceptible to mammary cancer, has been further investigated by Dr. L. Dmochowski. The factor, derived from any high-cancer strain mice, can induce breast cancer in susceptible strains although their genetic constitution differs from that of the strain from which the milk factor was obtained. Breeding females of low-cancer strain mice do not themselves develop breast cancer even after injection of large doses of the mammary tumour inciter. A proportion, however, of their offspring, both females and œstrone-painted males, develop mammary cancer. The effect of the milk factor was originally shown by foster-nursing young mice immediately after birth. Now, however, tumours have been induced by injecting relatively large doses of material into four-month old mice with well-developed mammary glands. The mammary tumour inciter has no direct influence on the incidence of lung cancer. The sarcomatous transformation of the stroma of cancers is probably independent of the milk factor as it takes place in lung tumours free of mammary tumour inciter. Dr. R. J. Ludford and Miss H. Barlow find that tissue of a lung tumour from a mouse without milk factor is just as active in causing fibroblastic growth in tissue culture as was tissue from similar tumours from mice containing the milk factor.

FORTHCOMING EVENTS

Saturday, September 15

Conference on "Friedel-Crafts Catalysts and Polymerisation" (in the large Chemistry Theatre, The University, Manchester), at 10.30 a.m. and 2 p.m.

Saturday, September 15—Sunday, September 16

Association of Special Libraries and Information Bureaux (at Portland Hall, Little Titchfield Street, London, W.C.1).—1945 ASLIB Conference.

Saturday, September 15

At 11.45 a.m.—Prof. J. D. Bernal, F.R.S. "Information Service as an Essential Factor in the Progress of Science"; at 2.30 p.m.—Symposium on "Links with the U.S.A.".

Sunday, September 16

At 3.30 p.m.—Discussion on "The Great Book Shortage—its Effect on Education, Research, Empire Intercommunication and the Re-establishment of Cultural Relations in Europe".

Wednesday, September 19

Physical Society, Colour Group (in the Small Physics Lecture Theatre, Imperial College, Imperial Institute Road, London, S.W.7), at 3.30 p.m.—Dr. Dora R. Ilse: "Methods for Investigating Colour Discrimination in Insects" (with colour films and demonstrations).

Friday, September 21

International Society of Leather Trades' Chemists (in the Lecture Theatre of the New Chemistry Building, The University, Leeds), at 2 p.m.—Prof. A. C. Chibnall, F.R.S. "The Contribution of the Analytical Chemist to the Problem of Protein Structure" (Second Procter Memorial Lecture).

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned

Borough Electrical Engineer—The Town Clerk, Town Hall, Barry, Glam. (September 21).

Physicists by firm of Domestic Refrigerator Manufacturers in South Midlands to train for position of responsibility in laboratory testing and research work—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting A.808.XA (September 22).

Civil Engineering Assistant—The Engineer and General Manager, Tees Valley Water Board, Corporation Road, Middlesbrough, endorsed 'Additional Civil Engineering Assistant' (September 24).

Two Supervisors (Production Engineer) for Telegraph Workshops at Calcutta, Jubbulpore and Bombay for manufacture of stores connected with Telecommunication Development—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting C 2484.A (September 28)

Lecturer in Agricultural Chemistry—The Secretary, Edinburgh and East of Scotland College of Agriculture, 13 George Square, Edinburgh 8 (September 29).

Lecturer in Colour Chemistry—The Secretary, Royal Technical College, Glasgow (September 29).

Principal of the Cardiff Technical College—The Director of Education, City Hall, Cardiff (September 29).

Technical and Industrial Assistant in the Industrial Department of the Liverpool Gas Company—The Personnel Superintendent, Radiant House, Bold Street, Liverpool 1 (September 30).

County Analyst—The Clerk of the County Council, County Offices, Preston, Lancs. (October 1).

Electrical Engineer—The Town Clerk, Municipal Buildings, Weymouth, endorsed 'Electrical Engineer' (October 1)

Professor of Bacteriology in the Department of Pathology (Ref. No. F 4802.A), and a Lecturer in Mechanical Engineering (Ref. No. C 2794.A), in the University of Cape Town—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (October 15)

Borough Engineer and Surveyor—The Town Clerk, Town Hall, Watford, Herts, endorsed 'Borough Engineer' (October 15)

George Holt Chair of Pathology—The Registrar, The University, Liverpool (October 31).

Head of the Engineering Department of Bournemouth Municipal College—The Director of Education, Town Hall, Bournemouth.

Graduate Physical Chemists with experience in the Printing Ink or Paint Industry to assist in the investigation of problems connected with the drying of printing inks from the physico-chemical aspect, and an Assistant with experience in scientific and technical abstracting—The Director of Research, Printing and Allied Trades Research Association, Charterhouse Chambers, Charterhouse Square, London, E.C.1.

Administrative Officer—The Secretary, British Scientific Instrument Research Association, 26 Russell Square, London, W.C.1.

Teacher of Building Subjects (Mathematics, Geometry, etc.), and a Teacher of Chemistry (with subsidiary Biology or alternative subject), at the Cambridgeshire Technical College and School of Art—The Chief Education Officer, Shire Hall, Cambridge.

Principal of the Lowestoft Technical Institute—The Chief Education Officer, County Education Department, County Hall, Ipswich.

Lecturer in Engineering Subjects (Mechanical) to Higher National Certificate standard—The Principal, Erith Technical College, Belvedere, Kent.

COLONIAL UNIVERSITIES AND THEIR FUNCTIONS*

IN announcing in the House of Commons on July 13, 1943, the appointment of two commissions to report on higher education in the British Colonies, the Secretary of State for the Colonies, Col. Oliver Stanley, said that he regarded educational advance and economic development as the twin pillars upon which any sound scheme of political responsibility must be based. If the goal of Colonial self-government was to be achieved, Colonial universities and colleges would have to play an immense part in that development. They would, first of all, have to meet the enormously increased need for trained professional workers which growing social and economic services would necessitate, providing the agriculturists, the engineers, the medical men, the teachers, the veterinary surgeons, and the specialists and technicians which the approach to higher standards of life entailed. They would be required to carry out an immense amount of research, and, finally, they would have a great extra-mural task of stimulating general progress throughout the areas of which they were centres, and encouraging the production of teachers from those who gain their knowledge and experience from their daily life.

The four reports which have now come from these two Commissions—for the report of Mr. Justice Asquith's Commission is supplemented by a report from the West Indies Committee of that Commission appointed with Sir James Irvine as chairman in January 1944 "to review existing facilities for higher education in the British Colonies in the Caribbean and to make recommendations regarding future university development for those colonies", while that of the Commission on Higher Education in West Africa, reporting under like terms of reference for that area, comprises both a majority report signed by the chairman, the Right Hon. Walter Elliot, and eight of the members, and a minority report signed by Dr. H. J. Channon, Sir Geoffrey Evans, Dr. Julian Huxley, Mr. A. Creech Jones and Dr. Margaret Read—are notable additions to the literature on the idea and purpose of a university. Considering, in accordance with the terms of reference of the Asquith Commission, the principles which should guide the promotion of higher education, learning and research and the development of universities in the Colonies, and exploring the means whereby universities and other appropriate bodies in Great Britain may co-operate with institutions of higher education in the Colonies to give effect to such principles, the Commissions have produced a series of reports in which the functions of a university, the relation between teaching and research, between academic and extra-mural activities are defined with a lucidity and a certainty that make these reports almost as pertinent to discussions on university development in Britain as in the Colonies. No better statement on the place of research could be desired than that to be found in the report of the Asquith Commission, and, quantitatively as well as qualitatively, the reports emphasize the close dependence of Colonial development and expansion in this field on the university expansion already contemplated in Great Britain.

---

* Report of the Commission on Higher Education in the Colonies (Cmd 6647.) Pp. 119. (London: H.M. Stationery Office, 1945) 2*s.* net.
Report of the West Indies Committee of the Commission on Higher Education in the Colonies. (Cmd. 6654.) Pp. 81. (London: H.M. Stationery Office, 1945.) 1*s.* 3*d.* net.
Report of the Commission on Higher Education in West Africa. (Cmd. 6655.) Pp. 190. (London. H.M. Stationery Office, 1945.) 3*s.* net.

Naturally, there is much common ground in these reports, and if the principles are dealt with rather more fully in that from the Asquith Commission, it should not be assumed that the same principles are not adequately emphasized in the others. Pointing out first that the four Colonial universities now in existence—the Royal University of Malta, the Hebrew University of Jerusalem, the University of Hong-Kong and the University of Ceylon—serve only a small proportion of those who live in the Colonies, the Asquith Commission bases the case for the establishment of universities in fresh areas on much the same argument as that used by Colonel Oliver Stanley. In the stage preparatory to self-government, universities have an indispensable part to play. To them we must look for the men and women with the standards of public service and capacity for leadership which self-rule requires. It is the university which should offer the best means of counteracting the influence of racial differences and sectional rivalries which impede the formation of political institutions on a national basis. Moreover, universities serve the double purpose of refining and maintaining all that is best in local traditions and cultures; and at the same time they provide a means whereby those brought up under the influence of these traditions and cultures may enter on a footing of equality into the world-community of intellect.

There is, in the Commission's view, no fundamental antithesis between liberal and vocational education, although the distinction has not yet been fully transcended in the universities of Britain. A university is in a far better position than a specialized institution to provide the courses, both in arts and science, which are the necessary preliminary to professional studies; and, while admitting that the promotion of popular instruction is most urgent, the Commission holds that the development of university education is the more imperative on that account, and as the first step urges the immediate setting up of university colleges. Such colleges would later, in accordance with the advice of an inter-university council, develop into universities serving appropriate areas.

The appropriateness of the area to be served by a university should be determined, according to the Asquith Commission, neither by size nor by population, but by the capacity to supply an adequate flow of students able to profit from higher education; and in accordance with this principle the Asquith Commission and the Irvine West Indies Committee specifically recommend the establishment of a University of the West Indies located in Jamaica. The Commission also supports the recommendation for the establishment of a university in Malaya, the proposal to develop Makerere College in East Africa to full university status, and the scheme for the development of Gordon Memorial College, Khartoum. The recommendation of the minority report of the West Africa Commission for the development of a single institution of university rank to serve the whole of British West Africa, entitled the West African University College and located at Ibadan in Nigeria, with a territorial college in each of the three main dependencies, appears to be more in keeping with this principle than that of the majority for the development of three university colleges at Ibadan, at Achimota in the Gold Coast, and at Fourah Bay in Sierra Leone.

Discussing next the range of studies, the Asquith Commission insists in the first place on the importance of a balance between professional and other studies, and accordingly the universities should include teaching in a fairly wide range of subjects. Every student, urges the Commission, should be given an opportunity to become aware of certain great conceptions. He should know something of the place of science in modern civilization and the use of scientific method; he should have learnt something of what is meant by sociology, so that he is aware of the other elements and forms of civilization. He should be enabled to gain some apprehension of what is involved in philosophy in its widest meaning, and some sense of the past as expressed in great literature and in the record of history. If his time at the university does not open his eyes to the existence of those great forces in modern life, the student, however expert in his own work, will have missed one of the great advantages which the university can offer him; here one may well wonder what proportion of students at British universities have really seized the opportunities to which the Asquith Commission points.

This vital principle appears largely to have been overlooked by the majority of the Elliot Commission, though both Commissions recognize the importance of a sound principle: the universities should be residential. Similarly, there is adequate recognition of the importance of providing fully equipped libraries and laboratories, and buildings such as union premises and halls of residence; and questions relating to staff and their environment and conditions of service are discussed with full understanding of the personal issues involved. In particular, the importance of adequate contact with academic life in Great Britain and elsewhere is emphasized and, like the Colonial Research Committee, the Commission fully appreciates the necessity of mitigating the isolation of the teacher or investigator in Colonial universities and colleges. As is pointed out, the whole future of the proposed new universities may depend upon the intellectual standards, wisdom and experience in academic administration of those who mould a college into a university, and carry the university through its first years. At the best, it will not be easy to obtain sufficient men and women of the right quality; and the importance of conditions of leave, of superannuation and secondment as factors in attracting and retaining academic staff of the desired quality is not easily overstressed.

It is clearly to the advantage of the new universities and university colleges proposed in these reports that the fullest contact should be established between them and other centres of research in the territories they will serve. Such contacts will do much, as the Colonial Research Committee has already noted, to counteract the isolation in which research must often be carried on in the Colonies; but the Asquith Commission has rendered a notable service to the establishment of right relations by the clear and emphatic way in which it defines the place of research in the Colonial universities, the field open for such research, and their relations with institutes of applied science. Equally lucid is the chapter in which the Commission develops its argument for an Inter-University Council for Higher Education in the Colonies; that chapter alone leaves no room for doubt as to the help which the universities of Great Britain can render in the developments proposed, and the value of such developments in forging the permanent intellectual links which are so desirable in the world to-day in the interests of peaceful progress.

The Inter-University Council recommended by the Asquith Commission would be a co-operative organization of the universities of Great Britain and the Colonies, charged in general terms with the two distinct tasks of co-operating with existing Colonial universities and of fostering the development of Colonial colleges in their advance to university status. The Commission has not overlooked the work being done in a more general field by the Universities Bureau of the British Empire, but considers a new body would be more appropriate for the discharge of its special function in connexion with the staffing of Colonial university institutions. Here the proposed Council, which would probably carry out much of its work through an executive committee, and would be provided with a permanent secretariat, including a full-time secretary of distinction and experience, and adequate office accommodation, should render considerable service. Other functions of the Council, in addition to acquainting itself with the present position and need of the Colonial universities, would be to facilitate arrangements for such institutions to receive visitors annually, to advise them on any matter of academic policy or research on which they sought its help, to assist the placing of Colonial students in universities in Britain, and to encourage Colonial studies in the home universities and thus stimulate both valuable contributions to the literature on Colonial problems, and an increasing interest in Colonial affairs among their students. The Council would also be available for fostering co-operation with the Dominions or India. But the Commission does not recommend that it should be asked to advise on the allocation to Colonial universities and colleges of grants from United Kingdom funds; for that function an entirely new body, which might be known as the Colonial University Grants Advisory Committee, should be created.

The Commission considers that it is essential that Colonial universities should be autonomous in the sense in which the universities of Great Britain are autonomous; although publication of an annual report, accompanied by a financial statement, and periodical visitation by a properly constituted authority are regarded as reasonable. A constitution is sketched for Colonial universities which offers the autonomy which secures the degree of freedom of teaching and research fundamental to a university, and the Commission examines with some care the period of transition from college to full university status before recommending that for the initial period students should enter for the London external degrees in continuance of the practice followed hitherto in several of the Colonial colleges. Degree-giving powers should be conferred on the Colonial institutions in due course; and the following qualifications are suggested: the staffs must have had adequate experience of work of a university standard; their conditions of work have permitted the active prosecution of research or original work; and a substantial number of students have completed satisfactorily the courses for degrees in a sufficient variety of academic subjects.

Finally, in this first part of its report, the Asquith Commission discusses the thorny problem of entrance qualifications, recommending the passing of a special college entrance examination; the provision of scholarships and financial assistance; the position of Colonial students in Great Britain, on which it recommends the extension of facilities for post-graduate studies, but the limitation of undergraduate study, as the colleges develop, mainly to those students taking exceptional subjects for which there is no local provision; and finance. As regards the last matter, it is considered that the establishment of a university in the West Indies will involve capital expenditure of about £1,130,000 and recurrent annual expenditure of £139,690; some additional funds will also be required by the Imperial College of Tropical Agriculture at Trinidad. Considerable additional funds will be needed by Makerere College in East Africa, and financial assistance in varying degrees may be required in Palestine, by the Royal University of Malta, and in Malaya and Hong Kong. The majority proposals of the Elliot Commission involve capital expenditure of about £1,500,000 and recurrent annual expenditure of about £250,000. The minority report, without entering into detail regarding the financial aspects of its proposals, does not suggest that the capital expenditure involved is likely to be less, but that the elimination of the multiplication of university facilities will result in a somewhat smaller annual expenditure.

Both Commissions recommend that part of the funds available under the Colonial Development and Welfare Act should be specifically assigned to the establishment of universities in the Colonies, and refer to the importance of a stable annual income for orderly development. The Elliot Commission contemplates that ultimately the West African Governments will bear the whole annual cost, and the Asquith Commission points to the desirability of the Colonial institutions building up endowment funds.

(To be continued.)

SOME CAMBRIDGE MEN

Alumni Cantabrigienses

A Biographical List of all known Students, Graduates and Holders of Office at the University of Cambridge from the Earliest Times to 1900. Compiled by Dr. J. A. Venn. Part 2: From 1752 to 1900. Vol. 2: Chalmers—Fytche. Pp. iv+ 594. (Cambridge: At the University Press, 1944.) £7 10*s*. 0*d*. net.

GLANCING through this volume, one gains the impression that the great majority of Cambridge graduates in the late eighteenth and the nineteenth centuries went into the church or into the professions of law and medicine; a smaller number became schoolmasters, entered the army or took up government service at home or abroad. The link between the clerical profession and an active scientific career was closer then than it is now, and it is not without interest that Charles Darwin, the outstanding figure in this volume, went to Cambridge to get a degree as a necessary preliminary to a career in the church. The Darwin family, with William, George, Francis and Horace, provides the best example of the inheritance of scientific power.

One of the most striking groups to be noted is that of the explorers. Doughty of *Arabia Deserta* may be coupled with Drake, the companion of Palmer and Burton. Cheadle with Viscount Milton was an early explorer of western Canada, while Clifton travelled with the Eskimos to the hunting-ground of the musk ox. The latter also broke new ground in Africa, as did Cotterill at Lake Chiassi and Crichton-Browne in Morocco. De Windt in his adventurous travels as a newspaper correspondent gained intimate knowledge of the insides of Siberian prisons. Polar explorers include Ferrar, geologist with Scott, and Fisher, astronomer to Parry on his expedition to find the north-west passage. Of Viscount Melville it is stated that he greatly encouraged Arctic explorations.

Martin Conway and E. A. Fitzgerald provide a link between explorers and climbers. Among the latter we find Cust, who made the first guideless ascent of the Matterhorn, Julius Elliott, also John Ellis, who was in the first ascent of the Finsteraarhorn. Other branches of sport are represented by R. F. and H. L. Doherty, Steve Fairbairn and Henry Foster, father of the seven Fosters of Oxford and Worcestershire. Admiral Fawkes was in a service not frequently claiming Cambridge men until the days of the 'Cambridge Navy' after the War of 1914–18. The Army is much more generally supported, especially through those who fought in that War. William Edwards of Trinity won the V.C. in 1883.

Coleridge, Edward Fitzgerald, Lowes Dickinson and Crabbe stand for literature in this volume. Politicians are numerous: Austen Chamberlain, Harold Cox, with his uncontrollable conscience, Clarkson the abolitionist, and Thomas Creevey of the "Creevey Papers" illustrate a wide diversity of types. Lorimer Fison, student of the Australian aborigines, turns the mind to James Frazer of the "Golden Bough".

The names of professional men of science occur in great numbers: we find two Astronomers Royal in Christie and Dyson, while Fallows was only prevented by an untimely death from being the first H.M. Astronomer at the Cape of Good Hope. The Royal Institution is represented by Humphry Davy, James Dewar and Michael Foster. Of mathematicians we may name Chrystal, Forsyth, W. K. Clifford and Augustus de Morgan. Entomologists include Baron Walsingham, who studied the smallest of moths, and Eltringham. Fitton worthily represents geology, W. R. Fisher Indian forestry, and W. H. Cole the Indian survey. John Elliott organized meteorology in India, other geophysicists being Dines the meteorologist, and Davison the seismologist. William Fairbairn, Dalby and Ewing were notable engineers, the two latter doing valuable work for the Admiralty in the War of 1914–18. Froude, the naval architect, has his name linked with the Froude tank at the National Physical Laboratory. Medicine has many names. Here we mention Walter Fletcher, organizer of the Medical Research Council, and Elliotson, who first used the stethoscope. The latter was of independent mind; he was one of the pioneers in the use of mesmerism, and he was the first to discard the knee breeches and silk stockings worn by his colleagues.

There remain for mention a few who catch the eye by something unusual in their careers. The Rev. W. B. Clarke discovered gold in New South Wales. Dunville was a keen racer in balloons, while Edward D. Clark kept an immense balloon for some days in the hall of Jesus College, finally launching it from the Cloister Court. The thirteenth-century arches in that Court were discovered by Osmond Fisher in 1840 and opened up by him fifty years later. The Hon. Richard Fitzwilliam gave the University the magnificent benefaction of the Fitzwilliam Museum. De Thierry, a French refugee, became an adventurer—"King Charles" of New Zealand. A less reputable adventurer was James Fennell, the actor, "who never paid his bills and passed his life between a palace and a prison". F. J. M. STRATTON.

ANTIGENS AND ANTIBODIES

The Specificity of Serological Reactions

By Dr. Karl Landsteiner. Revised edition. With a Chapter on Molecular Structure and Intermolecular Forces, by Linus Pauling. Pp. xiv+310. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1945.) 28*s*. net.

THE study of serological reactions has for years attracted many workers. There have been fierce controversies between the exponents of differing theories, and these controversies have stimulated both thought and work. During the last thirty years progress has been very rapid, and continues to be so, although relatively little work has been possible in Great Britain during the war years. The production of a revised edition of this extremely valuable book is therefore most welcome.

The new edition is very greatly expanded and almost completely rewritten because of the rapidity of the advances made during the eight years since the previous one. Further, two new chapters have been added; the one on antigen-antibody reactions and the other, written by Linus Pauling, on "Molecular Structure and Intermolecular Forces". In the former there is a historical survey of the theories of antigen-antibody reactions followed by a discussion of those current to-day. In the latter, Dr. Pauling gives a short, clear account of the relation of intermolecular forces to molecular structure which does, however, necessarily assume a considerable preliminary acquaintance with the subject.

Perhaps the most striking of the advances in immunology which have occurred in the last ten years are those, so much dependent on the development and use of electrophoretic technique, which have been made in the study of antibodies. It is interesting to compare the lack of definite knowledge and the contradictory evidence put forward at the time of the last edition with the accumulation of definite knowledge and the promise of continued advance which are so ably recorded in the corresponding chapter of the 1944 edition. In other parts of the subject no new technique of comparable importance to that of electrophoresis has been developed recently, and although numerous and important advances have been made there are not such great changes in outlook and prospects.

The objects of the book are in no way changed. A clear, concise, connected and authoritative account of this expanding subject has been given in a readable form. The bibliography is extensive; more than 2,000 references are given, and the author is more than justified in saying that he has attempted to offer a bibliography comprehensive enough for the use of workers in the field.

Unfortunately, in this edition, possibly to save paper, a system of abbreviations for journals and text-books is used in which, except in one case, a maximum of three letters is allowed. The reviewer has great difficulty in remembering even those initials which occur most often, especially when they bear so little relation to the full title, as 'Pr' for *Proceedings of the Society for Experimental Biology and Medicine*. This type of abbreviation is coming into wider use; but is certainly difficult for the reader and can only be justified as an emergency measure for saving paper.

Dr. Landsteiner and his colleagues have done a very large amount of very important serological work, much of it on antigens and serological reactions using simple compounds. It is fitting that a new edition of "The Specificity of Serological Reactions", prepared shortly before his death and printed posthumously, should be his last published work.

J. A. R. MILES.

MEASURING THE INFANT'S MIND

Intelligence Tests for Young Children

By Prof. C. W. Valentine. Pp. xii+68. (London: Methuen and Co., Ltd., 1945.) 4s. net.

IN this little book, Prof. C. W. Valentine has arranged a series of tests into a scale for assessing the 'intelligence' of children between eighteen months and eight years of age. For backward children the scale is recommended as suitable up to the age of eleven years. Tests are provided at half-yearly intervals up to the age of four, that is, during the period when mental growth is apparently more rapid, and thereafter at yearly intervals. Although the scale is intended chiefly for teachers, it is also meant for the use of that *rara avis*, an 'intelligent parent', eager to weigh the native talent of his offspring.

Apart from four new tests, all the material is borrowed, often with slight modifications, from Burt, Gesell, Stutsman and from the Merrill-Palmer and Terman-Merrill scales. In many cases new age assignments have been given. As in the Binet scale, the tests are scored on a pass-fail principle, and all test items are given equal weight, though no evidence is offered that they deserve it. A practical advantage is the simplicity of the apparatus required.

The reader may be surprised not to find in a book of this kind, where the emphasis is upon intellectual ability, any reference to the work of Dr. Charlotte Bühler, for Dr. Bühler's aim is to judge the degree of maturity attained by the child's personality as a whole, including its cognitive aspects.

A few of the 'tests', for example, bowel and bladder control, are scarcely tests at all in the sense of sampling responses in a standardized situation, for success in them depends on habits acquired under varied conditions of training. Without further evidence, one cannot therefore regard them as indexes of basic ability. The validity of the 'sentence completion' test at age six is also questionable, since it requires the highly specific ability to use two prepositions. One intriguing point is the author's statement (p. 10) that he found a "very close correspondence between very early tests (at only 12 or even 6 months) with tests of intelligence at 10 years and later". One would like to know precisely which tests were given at the age of six months to obtain such good predictions of later ability.

Intelligence testing originated in the practical aim of detecting inferior and superior educable capacity. During the school years the tests can be validated, because an independent criterion of what is measured by the test can be obtained—the teacher's estimates or school marks. In testing pre-school children, however, especially those less than two years of age, no such criteria are available and the question arises: What in fact do the tests measure? Almost certainly it is not just intellectual capacity, as might be the case in later years, but something affected by the child's whole make-up, including sociability, shyness, timidity and the affective dispositions generally. Prof. Valentine is well aware of this. The predictive value of intelligence tests at the early years is low, if only because of the low test reliability at these years; testing young infants is a painstaking task which makes it difficult to obtain consistent results. Although the test stimulus is designed to evoke a cognitive response alone, in reality, the child's entire personality reacts, and this influences the specific response to the test adversely or favourably. It would seem that Prof. Burt's observation made twenty-five years ago is unfortunately still to some extent true: "With infants, indeed, all tests and all estimates are bound to be more or less unsatisfactory" ("Mental and Scholastic Tests", p. 200).

Prof. Valentine admits that the age assignments are not altogether satisfactory, especially in the very early years. Thus the 'action agent' test at age three requires the infant to know the meaning of such words as 'gallops', 'aches', 'explodes', 'roars', etc. This surely deserves a higher age assignment than the Binet test in which the child is required to point to its nose, eyes, mouth, hair and knee, or the one in which the child has to put on his shoes. Some brief experiments by the reviewer confirm this view. Nevertheless, the scale may be warmly recommended for further experimentation and clinical use. It may be justified as a device for roughly gauging the general ability of young children, the estimates improving in accuracy as the child grows older. Much careful work is, however, needed, as the author would doubtless agree, before all the tests could claim a sound theoretical foundation.

JOHN COHEN.

ACHIEVEMENT IN MEDICAL SCIENCE

British Achievement in the Art of Healing

(Achievement Book No. 4.) By John Langdon-Davies. Pp. 36. (London: The Pilot Press, Ltd., 1945.) 2*s*. 6*d*.

THIS publication is one of a series of Achievement Books, the three preceding issues of which record British achievement in art and music, farming and in aircraft. The author of this issue, Mr. Langdon-Davies, pays a richly deserved tribute to modern medical work. "British medical science", he says in his foreword, "is loosely and illogically organized. In spite of this, there can be no doubt that the British medical profession rose to the occasion and solved the problems of war more successfully than they have been solved before in military history. . . ." Some of the problems which faced those others who were charged with medical service at the battle fronts and the means they adopted to meet them are also illustrated in this publication.

Mr. Langdon-Davies has had to contend with the inevitable limitations of space; but his vivid, experienced writing overcomes this difficulty and he is greatly aided by the remarkable photographs of which the publication is largely composed. The very large number of people, medical and non-medical, who contribute essential things to medical work nowadays, is aptly illustrated by the story of what happened to the shattered leg of a soldier in 1915, 1917 and 1940. In 1915 he very often died; in 1917 his life was more often saved, but he remained a cripple for life; in 1940 he was made fit again for duty and he will return to civil life as fit as anybody, even though a limb may have been lost. To this result medical men, scientific men and others all over the world have contributed, and it would be difficult to find a more magnificent example of the co-operation of men of all nations for the common good.

In the succeeding pages Mr. Langdon-Davies takes us through the training of the soldier, describing the improvements in his nutrition and the psychological examinations which improve morale by recognition of the fact that everybody is afraid in battle and by weeding out those whose mental histories predispose them to what used to be called 'shell-shock'. The treatment of shock and of the burns and injuries due to mines which have been so characteristic of this War, the story of blood transfusion and the management of pain and the now well-known histories of the sulphonamide drugs and of penicillin are well told and illustrated by excellent photographs. Plastic surgery, the closed-plaster treatment of injuries, rest and that vital stage in the healing process upon which increasing emphasis is now being laid, namely, rehabilitation, are each briefly described. The subsequent sections on tuberculosis and its detection by mass radiography, on typhus and its control by D.D.T., on malaria and venereal disease introduce us again to civilian life, for these are some of the gravest problems of that war which never ends, the war waged by disease against soldier and civilian alike. The achievement of that 'positive' health which is the subject of the last section is helped by no national mobilization; no Parliament votes fantastic millions to secure it; but to it modern science goes on quietly contributing new weapons which we can use or neglect as we wish. Publications like this should help all those who are trying to remove the suffering and loss caused by disease; for they spread sound knowledge; and knowledge removes the fear, apathy and uninstructed individualism which are among the root causes of so much ill-health and consequent inefficiency and unhappiness all over the world.

G. LAPAGE.

PHARMACOGNOSY

A Textbook of Pharmacognosy

By T. C. Denston. Fourth edition. Pp. xviii+594. (London: Sir Isaac Pitman and Sons, Ltd., 1945.) 27*s*. 6*d*. net.

THIS text-book of pharmacognosy has already found wide recognition among teachers and students of pharmacy. Its subject matter has grown from a laboratory manual intended for use in practical classes, and now comprises the requirements for the Chemist and Druggist Qualifying Examination of the Pharmaceutical Society of Great Britain.

The accounts of the various drugs are systematized and include biological and geographical sources, plant habits, methods adopted in cultivation, collection and preparation for marketing, chief constituents and instructions for practical work. Under the last heading are given schematic descriptions of the drugs and also qualitative chemical tests. The line-drawings are a valuable addition to this section of the work, emphasizing as they do the characters on which recognition is based, and acting as a guide to clear and accurate representation of morphological characters to the student in his own drawing. With the description and the drawings before him, the student can examine a commercial sample of a drug and then proceed to record his own observations.

The organized drugs are classified according to their morphological nature so that they can readily be compared. This is advantageous when points of difference have to be memorized for examination purposes. The drugs of animal origin are grouped together, and the unorganized drugs are arranged according to their similar properties. There is also useful information on drug constituents, stabilization, drying, preservation and adulteration of drugs. The subject matter of this edition has been extended to include the requirements of the addenda to the British Pharmacopœia. Halibut liver oil now receives notice; but the section on the vitamins has been deleted. Mention is made of the effect of war conditions on drug supplies. Additional reproductions of photographs add interest to an already well-illustrated text.

It is unfortunate that considerations of economy have necessitated production on paper of poorer quality than that of previous editions, and that, in spite of this, the price has had to be raised to 27*s*. 6*d*. from 20*s*. These are circumstances over which the author and publishers have no control, and they do not in any way impair the value of the information presented to the reader. The text-book is of convenient size and serves the purpose for which it is intended. It can be confidently recommended to students entering upon the study of pharmacognosy, and particularly to those who are candidates for the chemist and druggist qualification.

W. O. HOWARTH.

A RECENTLY DISCOVERED MANUSCRIPT BY LINNÆUS

By Dr. ANDERS GRAPE
Chief Librarian, University of Uppsala

It is a well-known fact in medico-historical research that the pharmacopœia, which was published in Stockholm in 1775 under the title of "Pharmacopoea Svecica", and at that time received with much enthusiasm both in Sweden and abroad, was prepared with the co-operation of Linnæus himself. The keen interest which the great botanist displayed in the production of a newer work, that might be substituted for the antiquated "Pharmacopœia Holmiensis", published in 1686, was also proved in many ways. (For the last-mentioned work see S. Lindroth in *Lychnos*, 1943, and E. L. Backman in the *Proceedings of the Uppsala Medical Association*, 1923/24.) That Linnæus already in his youth had his attention directed to this subject is shown by a small manuscript, which, like the bulk of his manuscripts left, belongs to the Linnean Society of London, and which just bears the title "Pharmacopoea Holmensis"; and in the correspondence exchanged for many years with his intimate friend, Dr. Abraham Bäck, president of the Collegium Medicum in Stockholm, the question is raised repeatedly from 1749 onward of a fresh and improved pharmacopœia. "You, my friend, who are the only person at the Collegium Medicum, if anything can be done, should touch up the pharmacopoeia", writes Linnæus on October 23, 1749, and a month later Bäck sent a list of the medicines of animal origin in the older pharmacopœia, from which he wishes to delete more than two thirds. After the College some years later (1753), in conformity with a royal decree, had seriously attacked the task of compiling a new "dispensary book", Linnæus probably followed the development of the scheme with constant interest; this is seen *inter alia* from the academic dissertations ventilated during his presidency; for example, "Plantæ officinales" (1753), "Censura medicamentorum simplicium vegetabilium" (of the same year), and several others.

It must, however, be said for the Medical College that serious difficulties arose which prevented a start being made with the work. A circular letter which had been sent to the medical faculties, physicians and apothecaries of the country had certainly caused all sorts of proposals and suggestions to be sent in, and contributions of varying value. These—the greater part of them preserved in MS. No. 151 at the Caroline Institute's Library (Stockholm)—had in their turn been sent to the members of the College; but when the manuscript proper was to be prepared, it consisted of a series of beginnings. In 1755 the various parts were certainly distributed so that each and every one should deal with a certain section, and it was also from the start agreed that in the first instance the British dispensatories, the Pharmacopœia Londinensis and the Pharmacopœia Edinburgensis, were to serve as prototypes. But as easily and often happens, when it is a question of collective work and divided responsibility, none seemed to take the matter seriously—at any rate nobody but the president, Bäck. His admonitory voice was heard time and again at the College, but his appeals to his colleagues were apparently without effect. After eight years had thus passed without the work having advanced, Bäck, in the year 1761, found it necessary himself to undertake the task of drawing up a proposal, which of course was received with approbation by his colleagues. For Bäck, who was very busy, partly as a medical practitioner, partly in his capacity of physician to the royal family, and was forced to stay for lengthy periods at the royal palaces outside Stockholm (Drottningholm, Ulriksdal), the acceptance spelled a serious amount of labour; and it can be understood that for that reason he was forced to seek assistance from his friend, Linnæus. The latter entertained a keen interest in pharmacology, particularly that part of it concerned with simples (simplicia), that is, materia medica; he had published Part 1 of a work dealing with the vegetable substances, and with a certain regularity there occurred a course of lectures on this subject in his academical teaching at Uppsala. At Bäck's request, he has now clearly undertaken to elaborate this part on Bäck's behalf. This is apparent from his letter to the latter, dated November 17, 1761, in which he begs Bäck insistently to procure a royal mandate for the patent of nobility which King Adolf Frederik had promised him, and for his part, he makes the following promise: "I on my part shall do my best that Materia medica will be to your credit and honour". In December of the same year he had sent to Bäck the promised manuscript; for he relates, in a letter of December 22, that he has sacrificed two nights for fair copying, which had therefore been done somewhat hastily, and that in such circumstances a further examination might be found necessary, etc.

As is easily understood, there has been some curiosity regarding the particular nature of Linnæus' manuscript; but it has been generally assumed that it had not only formed the basis for the section on materia medica as this appeared in the completed pharmacopœia when it was eventually published, but also that it was in every particular identical with this version. But there need no longer be any doubt about this point, since I have succeeded in showing that the original manuscript in question is still preserved in perfect condition, although it has hitherto been overlooked by investigators. It consists of 26 foolscap pages, comparatively well written, and is inserted in the previously mentioned volume No. 151 in the library of the Caroline Institute—perhaps the fact that the manuscript happened to be bound up with the previously noticed papers from the early years 1753–54 has contributed to its real nature being overlooked. In this case, too, it is the vegetable substances that are listed. The botanical kingdom quite as a matter of course occupied the foremost place in the heart of 'Princeps Botanicorum'. It should be added, however, that in another manuscript in the same collection (No. 42), there is a sheet in quarto which, in Linnæus' handwriting, contains a fairly hastily made summary of *Animalia* and *Lapidea*, that is, medicines derived from the animal and the rock kingdoms.

It has been possible for me now to show by a detailed comparison with the final version that Linnæus' contribution was not accepted without any further ado, but has been subjected to quite a thorough treatment, including both deletions and additions; but it is impossible to enter upon this matter here in detail. It is not without interest to have been able to ascertain that the revision was carried out by Anders Jahan Retzius, who, in 1769, assisted Bäck in his work on the pharmacopœia—for it was not until that year that the work was finished on Bäck's part. Retzius was eventually appointed professor at the University of Lund, where he carried out pioneer work in several branches of natural history and took the initiative in the foundation of the Royal Physiographical Society; he also founded a family which has produced several prominent natural scientists.

Although the manuscript here mentioned can scarcely be counted as particularly remarkable, the discovery must yet from a Swedish point of view be considered as valuable. For Sweden's national treasure of Linnæan manuscripts was, as is generally known, in the year 1784 so greatly reduced through the indifference of the Swedish authorities and the enthusiasm of James Edward Smith, that every addition is welcomed with satisfaction.

KILIMANJARO: CRATER FUMAROLES OF KIBO AND SEISMIC ACTIVITY DURING 1942-45

By J. J. RICHARD
Nakuru, Kenya Colony

IN view of the interest aroused by the activity of Kibo, after several groups of fumaroles had been located in its crater in 1942, it may be useful to give an account on further developments which have taken place on Kibo lately. Full reference to the activity of Kibo's fumaroles in October 1942 and their increased number in February 1943 (see Fig. 2) was made by the writer in a paper on Kibo, past and present, which was sent for publication in July 1943 to the *Journal of the East African Natural History Society*. This paper is as yet unpublished, through printing delays due to the War.

The occasional observations of 1942–43, made in spare time, and the scanty information obtained from the few mountaineers who visited the true crater, were of little value. Only patient observations, requiring time, would permit more precise deductions on events on Kibo. Despite great difficulties attached to regular observations made on a mountain nearly 20,000 ft. high, the indispensable periodical readings of the fumaroles temperatures of Kibo were arranged at the beginning of 1944. I was greatly assisted in this by the honorary secretary of the Mountain Club of East Africa, Mr. J. W. Smethurst of Marangu, who put at my disposal the well-known guide Johane, who accompanied me to Kilimanjaro on several occasions. Johane and an assistant, after having been shown how to take temperatures, ascended Kibo once every month (weather permitting) to record temperatures at five selected spots in the crater. They also checked up the amount of precipitation from four rain-gauges or totalizators installed by me in 1943 on Kilimanjaro, after consultation with Group-Captain A. Walter and suggestions made by Mr. C. Gillman in 1938. These rain-gauges were situated at altitudes of 7,200 ft., 9,400 ft., 12,500 ft. and approximately 16,000 ft. The instrument at 16,000 ft., being unsuited for the collection of snow, was brought down this year at 14,000 ft., on the saddle west of Mawensi, and I took up and installed on March 10, 1945, two snow-gauges at 16,000 ft. and 19,100 ft. for the British East Africa Meteorological Service.

The readings of the temperatures of the five fumaroles mentioned will be extended to nine in future. These five fumaroles were selected, among other reasons, for their positions south, south-east, south and west in different sectors of the crater, rather than for their high temperatures. These regular readings are sufficient to indicate important changes, should these take place. The monthly readings in 1944 give the averages shown in curve *A* of Fig. 3.

The slightly fluctuating curve shows a maximum temperature of 67° C. in February 1944 and a minimum of 47° C. in April 1944, making a difference of 20° C. The variation in temperature between the first and the last month of the readings is 6° C. (lower). When the precipitation figures *B* from the two highest stations—Peters hut, 12,500 ft., and Kibo hut, 16,000 ft.—are examined, it would seem that in the first months, the fumaroles, in other words, the thermic gradient of the volcanic plug of Kibo on the periphery of which (with the exception of fumarole No. 1) the fumaroles are placed, were affected by weather fluctuations. This is most unusual on deep-seated fumaroles as against so-called 'secundary fumaroles' the temperature of which may change very much according to the amount of precipitation. For Kibo, however, this seems disproved by the behaviour of the fumaroles later in the year.

The approximate upper-air temperatures (curve *C*) taken 20,000 ft. above Nairobi on the same dates as the temperatures of the fumaroles are unlikely to have been very much different from those prevalent above Kilimanjaro. They give the same evidence: that the outside influence on the fumarole temperatures is mere coincidence.

The figures obtained from the fumarole temperatures cover too short a period to allow a definite interpretation at this juncture. One has to keep in mind that fluctuations of a still greater order than

those found in 1944 may have occurred before. We know next to nothing of the behaviour of the crater even since the year 1927, when Dr. R. Reusch first entered it, or in 1930, when Mittelholzer flew over Kibo and published the first photographs of the crater. We have only Tillman's evidence of 1933 of "sulphur fumes discharging from the outer rim on the south side". My personal, general impression on March 10, 1945, was that of a diminution of the activity of Kibo crater since 1942. This is corroborated by the temperature readings in 1942 and in 1945. I recapitulate here some facts, for what they are worth, as evidence for the present:

On October 10, 1942, the temperatures of the eastern fumaroles, No. 2 (absent in June) averaging 91° C., were high. On February 2, 1943, the four points of issue of the fumaroles were much less marked and the fumes replaced by a light screen of water vapour involving only a small part of the slope. The average temperature was only 53° C. during 1944, 52° C., on March 10, 1945.

The south-eastern fumarole, No. 3, showed a temperature of only 37° C. in March 1945, compared with 60° C. in February 1942.

While in February 1943 the upper part of the southern slope was alive with fumes from fumarole groups 6, 7 and 8, there was very little vapour to be seen during March 1945. Temperature, February 1944, 90° C.; March 1945, 71° C.

The western fumaroles Nos. 9–11, when allowing for periodic small fluctuations as mentioned, showed approximately the same temperatures throughout 1944. In March 1945 they were of very similar aspect to that of 1942–43. This is also shown by photographs taken then and now.

Fumaroles 4 and 5 in the northern sector of the crater were in existence in October 1942 and February 1943. Their temperature was not measured, but in 1945 they do not appear to have changed from their behaviour of two years ago.

Spink's paper in the *Geographical Journal* of May 1944 mentions a temperature of 62° C. for the south and an average temperature of only 78° C. for the north-west fumaroles in July 1943.

From written evidence found in the Kibo hut book, I mention that of Lieutenant I. H. Ash, dated October 17, 1943. He "found no cause to put in further pegs to demarcate fresh volcanic activity". "Personally," he wrote, "I should hesitate to say the crater is becoming increasingly active to the point of eruption."

The above data are sufficient to suggest a striking decrease of activity between 1942–43 and 1945.

A fact worth mentioning is the seismic activity reported from Kilimanjaro at the end of 1943 and in the first months of 1944. Two tremors felt at the Kibo hut were recorded by several mountaineers. One, a vertical shock, took place on January 17, 1944 (report by Miss E. Lany). Another fairly strong one in the night of February 21–22 at the Kibo hut (report by Dr. Bucher) was noticed simultaneously at Peters' hut (report by guide Johane). More reports of tremors reached me during the beginning of 1944. Four of these were felt at Mashame, south-west of Kibo. The first occurred in mid-December 1943, the second in the night of January 10–11, 1944, the third in the night of January 28–29, 1944 (reports by Dr. Reusch), and a short tremor was felt at Mashame by Mr. R. Cunningham on April 9, 1944. These tremors were not reported from other localities in the vicinity of Kilimanjaro and were apparently local. At the dates mentioned, only microseisms, varying from extremely slight to slight, were recorded by the seismograph at Entebbe, often at different hours from the Kilimanjaro shocks. The epicentres of the local shocks are unknown, but may well have been on Kilimanjaro itself. This seismic unrest ceased as suddenly as it had started, and no new reports have come in during the last twelve months.

In January 1944 news came through that after the tremor of mid-December 1943 and the one of January 10–11, 1944, one or more long radial crevasses had been seen, from a distance, in the north-west glaciers of Kibo. Longitudinal or radial crevasses, apart from those appearing when a glacier, having been squeezed in a narrow bed, spreads out again, are most unusual. To see what had happened, I undertook an ascent from Mashame, between January 31 and February 4, 1944, along Jeager's route of 1906. A fissure such as reported could only have occurred in conjunction with tilting movements of the strata under the glaciers on the north-west flank of Kibo. During an extensive tour (which will be described elsewhere) nothing of an alarming nature such as disturbances of tectonic or volcanic origin could be detected. A rocky spur newly denuded of ice and snow was, however, apparent. This spur, about 500 yd. long, could easily be mistaken for a fissure in the ice, when seen at a certain angle, from a great distance. It was situated between Drygalski and Credner glaciers to the north of another patch bare of snow, above Penck glacier, where not long ago only a rock appearing through the ice, known in the past as Ravenstein, was in existence. These denudation effects are caused by the increasing rate of the diminution of the glaciers, a well-known phenomenon, as Meyer, Jeager, Klute, Gillman, Geilinger and others have pointed out during the past forty-five years. They are quite natural features in the prevailing climatic circumstances.

Observations on Kibo, both meteorological and volcanological, are continuing, and it is hoped that more data, together with those obtained from other volcanoes in East Africa, will prove useful in the future.

EMBRYOLOGY OF ANGIOSPERMS AS A FIELD FOR RESEARCH*

By Dr. P. MAHESHWARI
Head of the Department of Botany,
University of Dacca

In the history of angiosperm embryology there have been three distinct periods : the first, in which the chief aim was to unravel the chief facts regarding the development of the pollen and embryo sac, and the processes of fertilization and seed formation ; the second, in which interest centred largely round a study of comparative embryology and an evaluation of the data thus obtained for the improvement of the existing systems of classification ; and the third and latest in which embryology has become an experimental subject like cytology and physiology, where one tries to study the optimal conditions for the storage of the pollen and its germination ; the receptivity of the stigma, fertilization and fruit-setting and how far the normal processes of development can be influenced or altered by a change in the environment.

Descriptive Embryology

Most of our facts relating to the course of development of pollen, embryo sac, endosperm and embryo became clear towards the close of the last century through the researches of Amici, Schleiden, Hofmeister, Strasburger, Treub, Guignard, Nawaschin and others, and are now a commonplace in all text-books of botany. Very good summaries of this work were given by Coulter and Chamberlain[1] and Schnarf[2]. Little that is fundamentally new has been discovered during recent years, but there were several errors and misinterpretations made by previous workers which have been corrected and a mass of valuable information added regarding the structure and development of the male gametes, the types of embryo sac development, the process of fertilization, the origin and function of the endosperm haustoria and the development of the embryo[3]. Further work of this type would be welcome ; but results of greater value are to be obtained if attention is now focused on a comparative study of only one aspect of the life-history at a time, namely, male gametophyte, embryo sac, pollen tube, apomixis, polyembryony, the role of the endosperm in embryonal development, etc. Each of these requires the study of a vast amount of literature and often a technique somewhat different from that used for the rest. Finn's work in the Ukraine on the male gametophyte and that of Souèges in France on embryogeny are notable examples of what can be achieved by this method.

Phylogenetic Embryology

In the second period, which may be said to have commenced with the beginning of this century, embryology began to be used as a tool for the improvement of the existing systems of classification, the most important contributions in this line having come from Sweden, Germany, Austria and the United States. A great impetus was given to such studies by the publication of Schnarf's handbook entitled "Vergleichende Embryologie der Angiospermen", in which the author has summarized the existing state of our knowledge of the embryology of each family and added a number of valuable suggestions and comments at the end of each order.

That embryology can be a valuable tool for the systematic botanist may now be considered as established beyond doubt, for if we assume phyletic trends in the external morphology of the flower it is only natural to expect them also in such internal structures as pollen grains, embryo sacs, endosperm and embryo. Indeed, as a very competent embryologist[4] has recently remarked, the resemblances and differences in the embryological characters of the members of a family, although sometimes of such a fine type that they cannot be brought out either in words or in drawings but can only be appreciated under the microscope, are nevertheless of distinct value in delimiting the smaller groups and in determining their interrelationships within each order.

To mention certain specific instances where embryology has rendered an important service in the determination of the proper position of a family, we may first take the Empetraceæ, a family which has been placed by some authors in the Sapindales, by others in the Celastrales and by still others in the Monochlamydeæ. Samuelsson's work[5] has definitely shown, however, that its proper place is with the Bicornes, a group characterized by a number of well-marked embryological features which are also seen in the Empetraceæ : (1) presence of a fibrous layer in the anthers ; (2) presence of a glandular tapetum which does not become amœboid ; (3) pollen grains remaining together in tetrads ; (4) ovule with single integument and an ephemeral nucellus which disappears in later stages so that the embryo sac lies in direct contact with the integumentary tapetum ; (5) absence of parietal cells in the ovule ; (6) embryo sac of the monosporic eight-nucleate type with small ephemeral antipodals ; (7) a fluted hollow style which connects the lumen of the ovary with the outside and along which the pollen tubes make their way into the ovary ; (8) a cellular endosperm, with the first two divisions transverse and giving rise to a row of four cells placed one above the other ; (9) the formation of endosperm haustoria at both ends of the embryo sac, micropylar as well as chalazal ; (10) a single-layered seed-coat formed from the outermost layer of the integument, the remaining layers becoming absorbed during the growth of the embryo sac and embryo. There is no doubt that Samuelsson established his point of view fully and completely, and Hutchinson's[6] assignment of the Empetraceæ to the Celastrales is incorrect.

---

* Abridged and modified from the presidential address delivered to the Indian Botanical Society, January 1945.

Without going into details it may be further mentioned that on embryological and perhaps on other grounds as well the Lennoaceæ, which have sometimes been placed in the Bicornes[6], should be removed to the Tubiflorales[7], the Cactaceæ are best classed under the Centrospermales[8], the Podostomaceæ and Hydrostachyaceæ under the Rosales[9], the Moringaceæ under the Rhœadales[10] and the genus *Trapa* in the family Hydrocaryaceæ apart from the Onagraceæ. Recently, Schnarf[11] and Wunderlich[12] have suggested a number of rearrangements of the tribes and subtribes within the family Liliaceæ, which deserve the notice of the taxonomist. Space forbids a reference to several other works of a similar nature.

What has been written above is enough to show that with the main lines of latitude and longitude chalked out by the systematist it is possible for the embryologist, in co-operation with the cytologist and anatomist, to use this as a background and to help him in his work. Once a group has been assigned to its true place, every character that is studied will only serve to strengthen its position. On the other hand, if there are any discrepancies, they will be brought out in a more glaring fashion by the study of its internal characters (as these are less influenced by the environment) than the external.

There is great scope for phylogenetic embryology, as there are several families which have so far received little or no attention from this point of view. Special mention may be made of the following: Casuarinaceæ, Garryaceæ, Loranthaceæ, Balanophoraceæ, Aristolochiaceæ, Nymphæaceæ, Ceratophyllaceæ, Berberidaceæ, Magnoliaceæ, Myristicaceæ, Fumariaceæ, Droseraceæ, Zygophyllaceæ, Simarubaceæ, Callitrichaceæ, Burseraceæ, Hippocrateaceæ, Bombacaceæ, Sterculiaceæ, Salvadoraceæ, Dilleniaceæ, Dipterocarpaceæ, Flacourtiaceæ, Cornaceæ, Ebenaceæ, Myrsinaceæ, Pandanaceæ, Najadaceæ, Cyperaceæ, Palmaceæ, Cyclanthaceæ, Lemnaceæ, Flagellariaceæ, Xyridaceæ, Eriocaulaceæ, Stemonaceæ, Hæmodoraceæ, Dioscoreaceæ, Zingiberaceæ, Marantaceæ, Triuridaceæ and others. It is quite possible that a detailed knowledge of the embryology and internal structure of these families will in some cases give a new orientation to our ideas of their relationships.

Applied and Experimental Embryology

Coming now to the comparatively new field of experimental embryology, we find that the main directions in which work is being undertaken are: a study of the viability of the pollen and the optimum conditions for its storage and germination; the receptivity of the stigma; the rate of pollen tube growth under different conditions of temperature and humidity; the influence of external conditions on the interval elapsing between pollination and fertilization; the influence of X-rays, heat and chemicals upon the normal course of development; the induction of artificial parthenogenesis and parthenocarpy; and the culture of excised embryos *in vitro*. Considerable work on these lines is being done in the United States and the U.S.S.R. regarding the immense value of which in our breeding programmes there can be no question. We may hopefully envisage the possibility of having one or more 'pollen banks' in each country, where pollen of almost every plant of economic value will be stored under optimum conditions and supplied to recognized workers *gratis* or on a moderate charge. We shall be able to control sterility and unfruitfulness caused by premature or delayed pollination, a slow growth of the pollen tube or other similar causes. The culture of excised embryos under aseptic conditions has been of great help in overcoming the sterility which is inherent in certain interspecific hybrids as shown by the abortion of the embryos at an early stage of development if allowed to remain inside the ovule. This has given a new hope to the plant breeder for the creation and full development of many forms which were genetically possible but unobtainable due to other reasons.

Summing up, the embryology of angiosperms offers abundant scope for research not only on the descriptive side, which has not yet been exhausted, but also for the solution of many vexed phylogenetic problems and as an aid to the work of the plant breeder. In this last respect it comes in close contact with cytology and physiology and promises to be a study of great importance in the near future.

THE GEOGRAPHER AS HUMANIST

By Prof. W. FITZGERALD
University of Manchester

It is no longer possible, as in earlier days, for the individual researcher to investigate with equal facility all aspects of geography. Inevitably, as in other expanding branches of learning, there is concentration of effort in specialized directions, involving the inevitable risk that the essential unity of the subject and the effective inter-relations of its parts may be impaired. The complete geographer, like the complete historian, does not exist; though many a geographer of the generation which is now passing, by reason of his supposed range of interests, has been expected to qualify for the role.

Three recent papers in *Nature*[1], devoted to the purpose and method of geographical investigation, included particular reference to political geography, because of its special significance in a period of international crisis and widespread frontier changes. The political and the economic are the two humanistic aspects of geography which have most attracted attention, though there has been diffidence on the part of those concerned in providing a thorough-going presentation of the principles on which investigations have been made. If, however, the elucidation of political geography on its philosophical side is still without its proper place in the literature of the subject, what is to be said regarding the position of social geography, for which no statement of concepts of acknowledged orthodoxy exists! It is not surprising that confusion in teaching results, and that the social aspect of geography is occasionally identified with social anthropology which, in one guise or another, has sometimes been taught as 'human' geography.

Like every aspect of the subject, the physical as well as the humanistic, social geography is concerned with the spatial arrangement or pattern over the world of certain phenomena—in this case the phenomena which are of social, as distinct from political and economic, significance to man. They are treated, not in isolation, but in their interacting relationships with the total environment of man—an environment subject to, and undergoing constant transformation. Environment comprises not only the pattern of terrestrial phenomena within the habitat of man, in so far as they remain unaffected by human agency, but also the 'cultural landscape' which man has fashioned, with or without a plan, during his occupation. We think, for example, of the almost complete removal of the original forest-cover of western Europe in fairly recent historic time, and of ensuing agricultural and industrial utilization. Debate may long continue regarding the extent to which man, in his planned utilization of land, is subject to geographical controls: but it is generally accepted that his initiative is permitted adequate scope within the range of possibilities available at a given time. So much is agreed, even by those who contend that, in the realm of thought, man has the power to liberate himself from restrictions imposed by environment.

The most obvious transformation of environment by human agency is that which results from exploitation of economic resources. Less obviously and directly, environment is transformed in response to the application of political ideas. Political geography is dependent, in large measure, on the readiness of communities to seek economic, social and political segregation by raising frontiers against each other. A world without such frontiers seems at present unattainable, though rather because of the conscious rejection of federation as a way of political life than because of insurmountable geographical barriers. Apart from the study of all that is involved in the alignment of frontiers, the political geographer considers the effects of the political partition of territory on the life of the communities concerned. The selection of the site of a national capital, the geographical pattern of a national network of communications—these are two obvious examples of response, exemplified in every country, to the geographical limitations and opportunities imposed or offered by existing frontiers.

The manifestations of social life which contribute to the sum-total of human environment include, *inter alia*, the geographical distribution of population and of urban and rural settlements. In every continent, population is becoming more and more concentrated in large towns, with revolutionary consequences for social life. This is as true of oriental as of occidental civilization, as trends in urban growth in Britain, the United States of America, the Soviet Union, and Japan illustrate particularly well. The study of towns from the point of view of social geography is still in its infancy in Britain. It is but one aspect of an investigation which embraces the characteristics and relationships of all types of settlement, ranging from the city to the hamlet. In view of the present urgency of regional and town planning, it is not surprising that the geographer has received during the War a degree of official recognition unknown before. In his approach to the study of settlements, he recognizes that they are subject to an endless process of change, which may be one of either growth or decay according to trends prevailing within the region concerned. It is the dynamic quality in social, as in other aspects of geography, which most strongly appeals to the student of contemporary affairs.

Inseparable from the study of settlements is the geographical pattern of population distribution. It exerts a powerful influence upon the structure and organization of society, and provides the geographer with impressive, though not always conclusive, evidence of the comparative advantages for human occupation offered by the various regions of the world. Unfortunately, man is not free to settle the areas which are both geographically accessible and well-endowed by Nature. Political and social impediments, such as restrictive immigration laws, exist to arrest a natural tendency to migration from congested to emptier lands available for settlement. How to ensure that the population of a given area shall be, in density, neither excessive nor inadequate, taking into account both existing resources and their intended use, is the question on the answer to which social and economic planning largely depends. Such demographic terms as 'low' and 'high density' are frequently employed without reference either to prevailing social and economic standards or to comparative densities in other parts of the world, where similar geographical conditions prevail. There is obviously little value, from the geographical point of view, in comparisons of population density between communities of widely different social experience and habitat. A degree of density which is accepted as high for tropical Africa would be low according to Western European standards, even when comparison is restricted to non-industrialized areas of both zones. The fast-increasing 'urbanization' of population in every continent might suggest an approach to ultimate demographic uniformity throughout the entire world: but contrasts in population density between one region and another are assured for all time, if only because of wide variation between regions in regard to the economic possibilities that exist.

So far our reference to social geography as omitted the interaction between environment and manifestations of social intercourse, such as language and religion. To what extent do the geographical conditions of man's habitat intervene to affect the shape of human relationships? The fashion, not unknown among sociologists and economists, of studying society as if it existed in a geographical vacuum, is passing. Increasingly it is recognized that it is impossible to approach the study of society without reference to the territory on which its existence depends and with the horizons of which its traditions are harmonized.

Investigation of the inter-relations of the members of such comparatively primitive societies as the hunting-groups of Africa or the nomadic pastoralists of the steppes has usually welcomed the contribution of the geographer. It is quite unnecessary, however, for the latter to devote over much attention to the traditional social pattern of such peoples, in view of the rapidity with which, under pressure of new impacts, their social and economic experience is being transformed. It is now difficult to point to any part of the world where the life of primitives has not been revolutionized within the last half-century, through contact with peoples of contrasted, and generally superior, social and economic *techniques*.

Until recently, the Tatar-Mongols had maintained, almost unchanged for countless generations, their traditional social standards. Life had become stereotyped in its association with a grassland environment, which had known no important change throughout human time, save fluctuations in the abundance of natural pasture. The pastoral societies which, some decades ago, the French geographer, Demolins[2], described as peoples "without a history" have, in our time, grown accustomed to the complex social conditions of newly industrialized cities, such as Tashkent and Stalingrad. The modern civilization of the Euro-Asiatic steppe provides a particularly vivid example of the power of geographically mobile ideas to transform, by planned selection of available possibilities, an environment hitherto regarded as hostile to, and immune from, change.

The geographer recognizes that social organization, in so far as it is affected by geography, is a response, not only to local environmental conditions, but also to the degree of intimacy which exists between one region and another. Prof. Schrader's Herbertson Memorial lecture[3] of 1919 discussed the imperative need for the establishment of equilibrium between environment and society, and pointed to the temporary absence of such equilibrium over large parts of the continents as the principal cause of the world-wide social and political unrest of his time.

Search for evidence of the influence of environment on religion and language has had its appeal for one school of social geography. An earlier generation of environmentalists went so far as to advance geographical determinism in explanation of the Middle East zones of origin of the three great monotheisms —Christianity, Judaism and Islam. These religions, regarded as 'products' of a desert or semi-desert environment in each case, could not have arisen—according to the argument—under any other geographical conditions. Many, shocked by such doctrine, were yet prepared to admit that religious beliefs and practices are incomprehensible without reference to the social experience of the founder of the faith : which would seem to go half-way to the deterministic conclusion. Certainly each body of religious practices grows in association with a particular environmental setting, as George Adam Smith's classical work[4] offers impressive evidence. Moreover, when religious concepts spread from one region to another where social conditions are markedly different, they are inevitably modified in the process. Every religion of wide geographical range comprises, within its zone of influence, a diversity of concepts and practices which is intimately associated with the regional experience of its adherents.

Mere description of the distribution of religions and languages in terms of nations or political divisions is, in itself, a sterile enterprise. On the other hand, why their influence extends in certain geographical directions and not in others, why in certain areas they remain relatively 'pure' whereas in others they become 'mixed'—these are questions to the solution of which the geographer may be able to contribute from his knowledge of inter-regional associations. In these and other such inquiries it is the geographer's duty to ensure that the relationship of society with environment is not overlooked. Whether or not, on this basis, modern scholarship would concede the geographer's qualifications as a humanist, it should not be forgotten that by the Greeks of classical times he was accepted as such.

RECENT BIOLOGICAL WORK IN FINLAND

By Dr. G. H. BEALE
John Innes Horticultural Institution

DURING the War readers of *Nature* will have had little or no access to Finnish scientific publications ; nor under present conditions is it to be expected that there will be a rapid resumption of the exchange of periodicals in Europe. Consequently it is hoped that the following brief summary of recent Finnish biological work will be of value. A large quantity of material was kindly supplied to the author by Profs. R. Collander, H. Klingstedt and others. Space will not permit of the reproduction of more than a small proportion of this material ; in particular, records of applied work have been omitted, and of the mass of descriptive studies, only the most cursory mention can be made.

Finland is one of the few countries in Europe in which the vegetation over large areas has been comparatively little disturbed by agriculture or urban development. It therefore affords suitable terrain for the study of plant ecology and plant geography, and in fact a large number of papers have appeared on these subjects in recent years. Taxonomy also claims considerable attention in Finland, owing to the strong Linnæan tradition. Progress in other branches, however, may be attributed to the enthusiasm of certain individual workers ; for example, there is the plant physiological work on permeability at the Botanical Institute, Helsinki, under the direction of Prof. R. Collander, the biochemical work on nitrogen fixation in Prof. A. I. Virtanen's department[1], the cytological work in Prof. H. Federley's Genetical Institute, the animal physiological work under the direction of Prof. Paavo Suomalainen, and Prof. Pontus Palmgren's well-known ornithological studies. All these departments have been able to continue their work to some extent during the war years, though the Botanical Institute in Helsinki has suffered some bomb damage.

Plant Physiology

The plant physiological work of Prof. Collander's department is at present mainly concerned with two problems : (*a*) quantitative determinations of the permeability of plant protoplasts to dissolved substances, and (*b*) the active uptake of mineral salts by plant cells. V. Wartiovaara[2] has studied the effect of temperature on the rate with which eight different non-electrolytes exosmose from the giant cells of *Tolypellopsis stelligera* (Characeæ). He found a pronounced effect of temperature on the rate of permeation of these substances, the Q 10 being between 2·5 and 5·5 except for hexamethylene tetramine, where it was as high as 9. The temperature coefficients were found to be independent of lipoid solubility and permeation power of the substance used; but substances with smaller molecules, such as urea, ethylene glycol, urethylan, had lower Q 10's than substances with larger molecules.

Wartiovaara[3] has also studied the permeability of cells of *Tolypellopsis* to heavy water and methyl alcohol. These substances were found to permeate at approximately the same rate, and about two hundred times as fast as urea or twenty thousand times as fast as glycerol. It was also found that methyl alcohol permeates about ten times faster than substances of approximately the same relative lipoid solubility but greater molecular size, while heavy water permeates several hundred times faster than substances of corresponding lipoid solubility but greater molecular size. Molecular size is therefore a very important factor in permeation power in the case of extremely small molecules.

R. Collander, H. Lönegren and E. Arhimo[4] have found that neutral red, a rapidly permeating basic dye, permeates into the epidermal cells of *Allium* approximately twenty thousand times faster than urea, a non-electrolyte, in spite of the greater size of the neutral red molecules.

Collander[5] has also been investigating the selective absorption of various cations by higher plants, by growing some twenty species of phanerogams in nutrient solutions containing several cations in equivalent amounts, and afterwards determining the cation composition of the plants by Lundegardh's method of quantitative spectral analysis. It was found that rubidium and cæsium were taken up in approximately the same amounts as potassium; similarly strontium was taken up in the same amount as calcium. Thus the plants were unable to distinguish between potassium, rubidium and cæsium, or between calcium and strontium.

Collander[6] has also studied the distribution of several cations between root and shoot, and found that some cations (potassium, rubidium, cæsium) are approximately uniformly distributed; but that sodium and manganese in most species occur in higher concentrations in the root, and calcium, strontium and lithium in the aerial parts of the plant.

Animal Physiology and Developmental Mechanics

Paavo Suomalainen[7] has continued his investigations into the physiology of hibernation in hedgehogs. Arising out of the results reported in *Nature* in 1939, when he showed that hibernation could be artificially induced by injecting hedgehogs with insulin and putting them in the cold, Suomalainen has now found that the islands of Langerhans in the pancreas are hypertrophied during hibernation. He has also discovered that adrenalin secretion is much decreased during hibernation.

Osmo Tuurala[8] has been studying the movement of the pigments in the eyes of various Lepidoptera, which can be classified into at least five types according to their behaviour in this respect. In types considered to be primitive there is movement only of the iris pigment, while in more advanced types there is movement of other pigments also, namely, the retinula pigment, the pigment of the basal cell of the retinula (this moves in the opposite direction to the other pigments), and finally of the cell nuclei themselves. The primitive type is found only among night-flying Lepidoptera; dusk- and day-flying insects have the more advanced types.

Sykkö Pesonen[9], studying the nutrition of the hedgehog embryo, has found that during pregnancy, the corpus luteum secretes a hormone which is essential for the histiotrophic type of nutrition. This has been confirmed in mice also, by Annikki Vaalanto (unpublished).

Sulo Toivonen[10] has been investigating the *specific* induction effects obtained by implanting into newt gastrulæ small pieces of tissue from an unrelated species. Thus liver tissue from perch, guinea pig or viper (previously killed by treatment with alcohol) induced almost exclusively organs belonging to the anterior part of the head (anterior brain, nose, eyes, balancer). Kidney tissue from perch and guinea pig induced organs which in normal development occur in the posterior part of the body, from the ears backwards, especially secondary tails. Bird and viper kidney tissue, however, induced organs normally found in the posterior part of the head, that is, mid brain and posterior brain. Thymus gland tissue from the guinea pig often induced eye-lenses, a highly specific effect.

In a later publication, Toivonen[11] has reported on experiments with thymus gland tissue from guinea pigs of different ages, from which it is seen that the lens-producing substance predominates in four-months old thymus (or slightly younger), while in older glands the relative quantities of other substances increase.

Cytology and Genetics

Esko Suomalainen[12,13] has been continuing his study of the interrelation between parthenogenesis and polyploidy in the Otiorrhynchinæ and Brachyderinæ (weevils), and Blattoideæ (cockroaches). He has found that of the nine Finnish parthenogenetic weevils, there are one diploid, five triploid and three tetraploid species; while the bisexual species are all diploid ($2n = 22$). Suomalainen also reports a curious *gonomery* in the ripe eggs of some parthenogenetic species of weevil; for example, in a tetraploid species the different sets of chromosomes sometimes remain in separate groups—11 in one plane, 22 in another, 11 in a third; or 33 in one plane and 11 in another, etc.

Tarvo Oksala[14], studying meiosis in eight species of the dragon-fly *Aeschna*, has found that at spermatogenesis each bivalent normally contains one fully terminalized chiasma, while at oogenesis there are two chiasmata per bivalent, at opposite ends. There is a single X-chromosome in the male, which is sometimes attached to one of the autosomes, and always divides at the first meiotic division; a chiasma is never formed between the X and the medially situated centromere. On the basis of these studies, Oksala puts forward the unorthodox view that the first maturation division is an 'equational' one, at which the centromeres divide.

Prof. H. Federley[15], carrying on his long-continued cytogenetic researches on species and race hybrids in the Lepidoptera, has reported an unexpected chromosome situation in the hybrid between the European *Dicranura vinula* ($n = 21$) and the African *D. delavoiei* ($n = 31$). Both at spermatogenesis and oogenesis, at the first and second meiotic metaphases, only twenty-one (or sometimes a few more) chromosome 'units' are seen. In other hybrids in the same genus the number of chromosomes approaches the sum of the haploid numbers of the parents, since pairing at meiosis is very weak. Federley[16] has discovered a natural population of *Pygœra pygra* in which spermatocytes with the diploid number of chromosomes occur frequently. He is also preparing a general survey of chromosome numbers in the Lepidoptera.

E. Pfaler-Collander[17] has made a comprehensive cytological study of forty-five species of bugs of the family Lygæidæ and includes in her paper the novel feature of a key for the determination of the species by means of the numbers and relative sizes of the chromosomes.

Esko Suomalainen (unpublished) has made some observations on the inheritance of aneury in cats. He finds that it is due to a single gene, lethal when homozygous.

General

Space does not allow any account of the numerous publications on plant taxonomy, geography and ecology which have appeared in Finland during the War. Taxonomists will, however, be interested to learn of the completion of the monumental "Plantae Finlandiae exsiccatae a Museo botanico Universitatis Helsingforsiensis", by Harald Lindberg, which now comprises no fewer than 1,457 species. G. Marklund[18] has continued his investigations into such apomictic groups as *Taraxacum*, adding some thirty-two new Finnish species to those already known, making more than two hundred in all, and *Ranunculus auricomus*—*R. cassubius*, of which several tens of micro-species occur in Finland.

During the War more than eighteen papers on plant ecology or geography have appeared. Among them may be mentioned I. Hustich's work on the influence of climate on the forest limit, a subject of obvious importance in a country in which timber is of such enormous economic significance.

Prof. Pontus Palmgren and his collaborators have been carrying on their extremely careful and patient observations on the behaviour of birds. Among other studies, Palmgren[19] has investigated the day-and-night rhythm of migratory birds (for example, robins and thrushes) in captivity. He has found that during the winter and summer, the birds move about during the morning and evening ; while in the spring and autumn (the migration seasons), they move about at night. (Migration takes place at night.) Palmgren also has noticed individual peculiarities of each bird, which remain very constant.

Prof. O. Kalela[20,21] has been continuing his studies on population dynamics of mammals (such as lemmings) and birds (such as grouse).

Finally, some interesting work on insect ecology, inspired by the pioneer investigations of R. Krogerus, is in progress. Such, for example, is E. Palmen's study of the immense clouds of insects, containing some quite foreign species, which from time to time drift over the coast of Finland.

In conclusion, it is with regret that one must record the deaths of F. Elfving (1854–1942), who was for so long head of the Botanical Institute of the University of Helsinki and was the first plant physiologist in Finland ; K. Linkola (1888–1942), well known for his work on the influence of culture on the vegetation and flora of the district north of Lake Ladoga ; and A. K. Cajander (1879–1943), author of the theory of forest types.

OBITUARIES

Dr. J. Davidson

THE unexpected death of Dr. J. Davidson, at the age of sixty, came as a shock to his many associates in Great Britain and in Australia.

Davidson graduated from the University of Liverpool in 1908, taking his D.Sc. degree in 1915. He worked as a research scholar at the Imperial College of Science and Technology, London, and with the Ministry of Agriculture, his work also taking him abroad to Paris, Berlin and Florence. He served during the War of 1914–18 as captain in the R.A.M.C., carrying on special entomological work particularly on the relations between mosquitoes and malaria. His work in Sinai was mentioned in dispatches.

In 1920, Davidson joined the staff of the Rothamsted Experimental Station in the newly formed Entomological Department under A. D. Imms. His work was concentrated on the biology of the bean aphis, *Aphis rumicis*, and he also collaborated with H. Henson in studying the effect of various chemical substances on aphis infestation. The materials were either injected or watered on to the sand in which the plants were grown, pyridine proving fatal to the aphids at strengths which were harmless to the plants. Observations in the course of this investigation led to the intensive work on the relation between boron and plants later carried out in the Botanical Department of Rothamsted. Besides numerous papers on the subject, Davidson published in 1925 an important monograph listing the British aphids.

In 1928, Davidson accepted the post of entomologist to the Waite Research Institute at Adelaide, Australia, and soon after was also appointed as professor of entomology at the University of Adelaide, holding both posts until his death. His Australian work again took a very practical bias, and during his first few years in the country, he dealt with a number of insect pests which were the cause of considerable economic loss. Thrips, Collembola, 'white grubs' (larvæ of beetles of the family Scarabæidea), eelworms, and other pests attacking pastures, cereals and fruit came under investigation, and control measures were suggested. Later he gave considerable attention to locust and grasshopper outbreaks, arising from a widespread plague of grasshoppers in South Australia during 1933–35. This led to more generalized work on the ecology of insects, particularly in relation to climatic conditions, most of his later papers dealing with various aspects of this subject.

Soon after taking up work at Rothamsted, Davidson married Johanne Therese Hornemann, one of a very musical Copenhagen family. Three sons went out with them to Australia, a girl being born later. Their musical evenings at Harpenden will long be remembered by those who were fortunate enough to be invited. W. E. BRENCHLEY.

Mr. R. C. Porter

MR. RALPH CLASSON PORTER, for thirty-seven years senior lecturer in the Department of Mechanical Engineering, University of Birmingham, died at his home in Northfield on July 28, in his seventy-fourth year.

Mr. Porter was the son of the Rev. James Nixon Porter and was born at Heatley, Warrington, on August 14, 1871. He was educated at Clifton, and afterwards at the University of Liverpool, where he obtained a first class honours degree in engineering in 1892. After graduation he was for three years a premium pupil with Messrs. Beyer, Peacock & Co., Ltd., of Gorton, Manchester, and on completion of his pupillage spent a short time with the Belfast and Northern Counties Railway, obtaining running experience on the footplate. His enthusiasm for locomotives and locomotive engineering was to remain with him throughout his lifetime. For nearly four years after leaving the railway he was assistant manager of the rolling mills of the Frodingham Iron and Steel Company.

In 1899 Mr. Porter took up academic work and was appointed lecturer in engineering at the Polytechnic School of Engineering in Cairo. He left Cairo in 1901 when he was appointed lecturer in mechanical engineering at the University of Birmingham under the late Prof. F. W. Burstall. His experience in Cairo made him especially sympathetic and understanding of the difficulties of students from the East who studied at Birmingham.

In 1901 the Department of Mechanical Engineering was at Mason College, and it devolved upon Mr. Porter to design and lay out the engineering workshops and the power station for the Department in the new University buildings at Edgbaston. The power station was responsible for the supply of heat, electric power and lighting to the whole of the University buildings, and was in addition used as a heat laboratory. During the period 1914–18 the University buildings at Edgbaston were used as a military hospital, Mr. Porter being responsible for the maintenance and for the installation of the additional plant required. When normal conditions returned, he reorganized and re-equipped the Department on a new site near the power station.

Throughout his long career as senior lecturer and director of the power station, he took a keen and active part in University life, and until his retirement represented the non-professorial staff on the University Council.

He leaves a widow and two sons, his eldest son, who was a research engineer with the L.M.S. Railway, having predeceased him.

WE regret to announce the following deaths:

Dr. William Cramer, who was associated with the Imperial Cancer Research Fund during 1914–39, on August 10, aged sixty-seven.

Mr. R. A. Rye, Goldsmiths' librarian of the University of London during 1906–44, on September 14, aged sixty-eight.

Dr. B. O. J. Schrieke, delegate for the Netherland Indies at the United Nations Conference and formerly professor of social anthropology in the University of Amsterdam and later director of the Anthropological Section of the Colonial Institute, Amsterdam, aged fifty-five.

Prof. C. E. Spearman, F.R.S., emeritus professor of psychology in the University of London, on September 17, aged eighty-two.

NEWS and VIEWS

Research and Development in the United States

IN his message of September 6 to Congress, President Truman called for the establishment of a new Federal Agency to implement the recommendations of Dr. Vannebar Bush's recent report, "Science—the Endless Frontier" (see *Nature*, August 4). The development of atomic energy, said the message, is a clear-cut indication of what can be accomplished by the universities, industry and Government working together. Vast scientific fields remain to be conquered in the same way to derive the full profit in the future from what we have learned. The President urged upon Congress the early adoption of legislation for the establishment of a single Federal research agency which would discharge the following functions: promote and support fundamental research and development projects in all matters pertaining to the defence and security of the United States; promote and support research in the basic sciences and in the social sciences, as well as in medicine, public health and allied fields; provide financial assistance in the form of scholarships and grants for young men and women of proved scientific ability; co-ordinate and control scientific activities of Federal departments and agencies; and make fully, freely and publicly available to commerce, industry, agriculture and academic institutions the fruits of research financed by Federal funds. The message also called for an additional contribution of five hundred and fifty million dollars from the United States to the United Nations Relief and Rehabilitation Administration, and appealed for legislation for the early resumption of a vast programme of public works sponsored by the late President Roosevelt, urging that similar projects to the Tennessee Valley Authority should be undertaken for the development of the Columbia, Missouri and Arkansas Rivers and the central valley of California. "We shall seek," said the message also, "under the procedure prescribed in the lend-lease act and in subsequent agreements with other Governments, to achieve settlements of our war-time lend-lease relations which will permit, generally, a sound world-wide economy and will contribute to international peace and to our own national security."

Operational Control of Electricity Supply Systems

Supervisory equipment for the remote control of plant has proved to be thoroughly reliable and to facilitate efficient operation of electricity supply systems. In a paper read in London on March 14 by W. Kidd and E. M. S. McWhirter before the Institution of Electrical Engineers, the authors give the reasons for, and the steps taken to develop, the common-diagram control system, which enables an almost unlimited number of substations, etc., to be controlled completely from one diagram and control panel, and is sufficiently flexible to cater for the growth of an undertaking. It describes a wall-type system diagram which automatically indicates which substations have changed conditions, and therefore the area involved in any disturbance. The system diagram is equally extensible to accommodate new feeders and substations with a minimum of operating disturbances. Particulars of the circuits and apparatus, and comparisons of floor area, pilot and cost economies are given in the paper, together with information relating to an installation dealing initially with seventy-eight substations, to which others are being added.

The authors believe that, by the development of the ideas explained in the paper, the use of supervisory remote-control equipment has been extended on normal automatic-telephone switching practice to a wider application than was practicable with individual systems for large numbers of substations. This results in an economy of cost of equipment, of cost for control buildings, and of effort of the control staff. Operational control of large electricity supply systems will undoubtedly produce new requirements and problems as industrial, traction and domestic loads increase; but it is believed that, in the system described, a basis for meeting these requirements without adversely affecting present facilities has been provided.

Quaternion Centenary Celebration

The centenary of the discovery of quaternions by Sir William Rowan Hamilton has already been the subject of an article in *Nature* (**152**, 553; 1943). The Royal Irish Academy has now published (*Proc. Roy. Irish Acad.*, **50** A, 69; 1945) a record of the celebration in Dublin on November 8, 1943, which was attended by Mr. de Valera and two of his Ministers. Owing to the War, representatives of science from outside Ireland were unable to be present in person, but some of them sent messages or articles. The late Prof. G. D. Birkhoff of Harvard stressed the part that Hamilton's ideas played in the development of mathematics in the United States. Vectorial theory could be regarded as, to a large extent, latent in quaternions, like a fine melody in a great symphony. Vectors were more useful in classical physics, quaternions in the special theory of relativity, and tensors in gravitational relativity. Mathematicians and theoretical physicists should study all three with their historical development.

Sir Edmund Whittaker gave an account of the sequence of Hamilton's ideas, pointing out the gaps and apparent lack of harmony in existing accounts. With regard to Hamilton's recognition of the necessity for non-commutative multiplication, Whittaker says: "This was the supreme moment in the history of mathematical symbolism. It began the creative process which yielded not only quaternions, but all the other systems which broke away from the old rules —Cayley and Sylvester's matrices, Boole's symbolic logic, Grassmann's *Ausdehnungslehre*, Gibbs's dyadics, and the Heisenberg-Dirac algebra of quantum mechanics. Dr. A. J. McConnell dealt with the many distinguished members of Trinity College, Dublin, in the first half of the nineteenth century, including the mathematical physicists Hamilton, Lloyd, MacCullagh, Jellett and Haughton, the astronomer Brinkley, and the geometers Salmon, Booth, Hart, Charles Graves, Ingram and Stubbs. Dr. McConnell also printed the hitherto unpublished manuscript by Hamilton containing his first account of quaternions, written on the evening of the discovery. There are three other papers which demand more technical knowledge from the reader: "Quaternions and Matrices", by Prof. A. W. Conway; "A Modern Presentation of Quaternions", by Prof. F. D. Murnaghan, of Johns Hopkins University; and "The Icosian Calculus", by the Rev. J. R. Colthurst. The volume contains two plates: one a reproduction of an etching of Hamilton, the other a photograph of the first entry in his note-book of quaternion formulæ.

Mechanization of Sugar Beet Production

The Ministry of Agriculture, in agreement with the Ministry of Food, is sending a small mission to North America this autumn during the sugar beet harvest season to study progress there in research and development work on the mechanization of sugar beet cultivating and harvest. The party will consist of Mr. J. Bradley, principal scientific officer in charge of the engineering side of the National Institute of Agricultural Engineering; Mr. W. J. West, senior scientific officer on the agricultural side of the National Institute of Agricultural Engineering; Mr. F. E. Thornhill, agricultural officer from the British Sugar Corporation factory at Allscott, Salop; and Mr. H. S. Taylor, agricultural officer from the British Sugar Corporation factory at Brigg, Lincs. They will visit the principal growing areas in North America during harvest and will study practical operations in the field and in the factories in addition to the research and development work being undertaken by university centres, sugar factories and agricultural machinery manufacturers. It is hoped that the information and experience gained will be of considerable value to workers in this field in Great Britain, at a time when the problem of developing suitable machinery to meet the needs of British growers at the peak periods of cultivation and harvesting is of vital urgency. Special attention will be devoted to problems connected with the segmentation of sugar beet seed, the development of beet seed drills and the mechanization of sugar beet harvesting.

Narcotic Drugs

The two plants from which the raw materials of all the manufactured drugs covered by the International Conventions of 1925 and 1931 originate are the opium poppy and the coca bush. The former is used for the manufacture of morphine, heroin, codeine, dionine and other drugs, and the latter for the manufacture of cocaine. Unlike opium, coca leaves are little used in the form of medicinal preparations but are used in large quantities in the preparation of non-narcotic beverages. The Central Opium Board of the League of Nations, in a 32-page report prepared by Mr. L. F. Atzenwiler entitled "Pre-War Production and Distribution of Narcotic Drugs and their Raw Materials" (New York: International Documents Service, Columbia Univ. Press. London: George Allen and Unwin, Ltd., 1944. 50 cents.) summarizes and analyses the mass of world-wide material which the Board has received. The report shows the importance of each country as a producer, and the quantities and methods of disposal of the raw materials and manufactured drugs, by both producer and consumer countries. The world productions of raw opium and morphine, for example, were 18,504 tons and 137,360 kgm. respectively during the period 1934–37. Although such details will chiefly interest technicians, the main facts, trends and conclusions should be of great value as basic material for those concerned with future international work in this field.

Treatment of Arterial Injuries

The Medical Research Council's War Memorandum, No. 13 (H.M. Stationery Office, 1944), on "Arterial Injuries" has been prepared by the Vascular Injuries Sub-committee of the Council's War Wounds Committee. It is intended for those who have only a limited experience of the early treatment of arterial wounds. It carries the authority of the eleven leading British surgeons who sit on this sub-committee, and shows how far surgery has advanced in recent years. The pamphlet is divided into sections on anatomy, symptoms, treatment in forward battle areas or in hospitals where specific operative treatment is possible and on the management of limbs in which the circulation has been impaired. Appendixes deal with the technique of the suture of completely or partially divided arteries, the administration of heparin, the technique of blocking the sympathetic nervous system in the arm or leg and the writing of notes on vascular injuries. Primarily useful to surgeons, this pamphlet will no doubt interest others who may have to deal with this kind of injury in peace-time as well as in war.

Spicules on the Sun

The March issue of *Sky and Telescope* contains a brief notice of solar spicules, which are very small spike-like prominences most commonly seen in the polar regions of the sun. They have previously been seen during solar eclipses; but the coronagraph makes it possible to carry out daily observations of their numbers and duration. Dr. Walter O. Roberts is in charge of the observations made at Harvard College Observatory's Fremont Pass station at Climax, Colorado, and he has found that the spicules last only four or five minutes from the time of detection until they fade out completely. A spicule is brightest just before it attains its full height, and after reaching its maximum elongation it begins to fade out without any perceptible motion. Their average width is about 4,500 miles and most of them are only a few thousand miles high. The largest spicule sometimes lasts eleven minutes, and some of the smaller ones about two minutes. At times as many as twenty-five spicules have been seen simultaneously in a 60° arc of the sun's polar limb. They are not seen in disturbed regions of the sun, and they show material flowing outward from the lower layers of the atmosphere; this is in contrast to the ordinary solar prominences, which show material when it is falling inward to the sun's surface.

Smithsonian Publications

The Classified List of Smithsonian Publications Available for Distribution, May 1, 1925, compiled by Helen Munroe (Publication A.3802, Smithsonian Institution, Washington), contains only such works as can now be supplied by the Institution. It is not a complete list of all Smithsonian publications issued to date, and in particular publications of the United States National Museum and of the Bureau of American Ethnology are not included. The papers are arranged by subjects alphabetically, and the series in which they appeared are indicated. Those in the series of Contributions to Knowledge and Miscellaneous Documents are not public documents, but are available in printed editions and distributed without charge to public libraries, educational establishments and learned societies. They are supplied to other institutions and to individuals at the prices indicated. The Smithsonian Report volumes are distributed gratuitously to libraries and individuals throughout the world; but many of those of which the Smithsonian edition is exhausted can be purchased through the Superintendent of Documents, Government Printing Office, Washington. Applicants to the Institution should state the grounds for their request, as the Institution can only supply the papers as an aid to research or studies in which applicants are specially interested.

Announcements

The Committee of Privy Council for Medical Research has appointed Prof. P. A. Buxton, professor of medical entomology in the University of London, and Sir Alexander Fleming, professor of bacteriology in the University of London, to be members of the Medical Research Council from October 1, 1945.

Mr. J. Stewart Cook has been appointed organizing secretary of the British Association of Chemists as from July.

The life and work of the late Major Charles E. S. Phillips, secretary of the Royal Institution during 1929–45, will be commemorated at a meeting at the Institution on October 1 at 5 o'clock. Lord Rayleigh, the president, will take the chair and short addresses dealing with various aspects of Major Phillips' life and his connexion with the Royal Institution will be given by Sir Robert Robertson, Sir Richard Paget, Mr. R. S. Whipple, Prof. W. V. Mayneord and Sir Henry Dale.

The Imperial Institute is arranging a series of lectures on recent progress in geological investigation and mineral developments in the Colonies. Each lecture will be devoted to a particular territory and will be given by a recognized authority. The first of the series will be given on October 31 at 3 p.m. by Dr. F. Dixey, director of the Geological Survey of Nigeria, on "Nigeria, Its Geology and Mineral Resources". The second lecture in the series, by Dr. N. R. Junner, director of the Gold Coast Geological Survey, will be given in December, and others will follow.

The Hertfordshire Institute of Agriculture has unbound copies of *Nature* from 1926 onwards. Those dated up to the beginning of the War are available to bombed-out research institutions and libraries on payment of cost of packing and transport. Further information can be obtained from Mr. H. W. Gardner, Hertfordshire Institute of Agriculture, "Oaklands", St. Albans, Herts.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Artificial Production of Ergot in the Tropical Plains of Bengal

THE British Ministry of Health in 1941 made an appeal[1] for the cultivation within the Commonwealth of ergot, supplies of which had come hitherto from Central Europe, Spain and Portugal, where it occurs naturally. Wales and certain west coast places in England, and New South Wales, have taken up trial cultivation with a certain degree of success. English results are not definitely known; but the Australian ergot has an "alkaloid content well above the minimum standard provided in B.P., i.e. 0·05 per cent"[2]. In India, the Madras Agricultural Department[3] has taken up its experimental cultivation in the Nilgiri Hills and the produce has a similar alkaloid content.

It now appears that the localities selected both in Madras and New South Wales had a temperate climate and an altitude of a few thousand feet similar to that of its natural habitats. The importance of the present investigation lies in the fact that it is the first record of the artificial production of ergot sclerotia on rye plants under tropical conditions. The experiments were conducted at Calcutta: altitude 18 ft.; the shade temperatures, max. 67°–101° F.; min. 55°–62° F.; with a daily average max. temp. 85·1° F., min. temp. 64·3° F.; a total rainfall of about 13 in. during the period of investigation (from 17.10.44 to 23.3.45), the normal annual rainfall being about 65 in.

Four small plots, manured only with moderate doses of cow-dung, were sown with rye. The plants gave a good stand, and when they flowered they were sprayed by a hand atomizer with a water (sterile distilled) suspension of the conidial spores of the ergot fungus, *C. purpurea*, which was initially obtained by culturing bits of ergot from a commercial source. The sclerotia were first sterilized by steeping for a few seconds in absolute alcohol, then in 0·1 per cent mercuric chloride for five minutes followed by washing in sterile distilled water. Bits of sclerotia were then put in culture media and they gave rise to mycelial growth at 15–25° C., followed by sporulation in Leonian's, Kirchhoff's, rye agar, and wheat agar media.

Plot No.	Sowing date	Flowering date	Spraying date	Total no. of sprayings	Interval between sprays	Harvest date	% of infected tillers
I	17.10.44	24.1.45	31.1.45	6	24 hr.	14.3.45	89
II	30.10.44	2.2.45	7.2.45	6	24 hr.	20.3.45	86
III	15.11.44	4.2.45	8.2.45	8	24 hr.	25.2.45	85
IV	29.12.44	5.2.45	12.2.45	8	24 hr.	3.3.45	81

Spraying was done either in the morning, noon or Afternoon; the noon spraying was preceded by a sterile water spraying one hour earlier, in order to keep the glumes more open to facilitate infection.

Good infection of individual rye flowers occurred on all the plots, being externally evident by secretion of shining drops of light cream-coloured, thick 'honey-dew' drops at the tips of infected spikelets seven to ten days after spraying. This 'honey-dew' stage continued for some weeks. Three to four weeks from the first spraying, small purple sclerotia were found growing out through the glumes, replacing the ovaries. In seven to nine weeks from the first spraying, the sclerotia matured. They were now deep purple to almost black, hard, horny, pseudo-parenchymatous structures emitting a fishy smell. The number of sclerotia varied from 1 to 33 per panicle, 3–6 being the common number; when the number was greater their size was smaller. The biggest sclerotia was 3·6 cm. in length, 0·4 cm. in diameter, and weighed 0·248 gm. when air-dried. The yield obtained is also considered good.

ERGOT SCLEROTIA ON RYE EAR-HEAD.

The sclerotia were then harvested by hand picking and sent after six weeks storage at room temperature (20°–25° C.) in glass bottles for chemical assay to the director of the Bio-Chemical Standardisation Laboratory, Government of India, Calcutta. The results of the analysis reported by him is as follows: "The Ergot Sclerotia were assayed according to the method given in the 6th Addendum to B.P., 1943, and I find that ergots are of good quality, having a total alkaloid content of about 320 mg. per 100 gm. (B.P. figure: not less than 200 mg. per 100 gm.) and the Ergometrine content to be 72 mg. per 100 gm. (B.P. figure: not less than 30 mg. per 100 gm.). It will therefore be seen that these ergots are of a better quality than the B.P. standard Ergot".

Thus very good quality ergot can be easily produced in the plains of the tropics by artificial spraying of rye flowers with the ergot fungus spores, and if taken up commercially India will be in a position to export after meeting her own requirements.

Our thanks are due to Dr. B. Mukherji, director of the Bio-Chemical Standardisation Laboratory, for assaying the alkaloid content of our ergot, and to Prof. J. C. Sen Gupta, head of the Department of Botany, Presidency College, for his continued interest and help. Further, the senior author wishes to thank the Bengal Immunity Co., Ltd., Calcutta, for placing at his disposal the staff and the finances for this investigation.

J. C. SAHA.
S. K. BHATTACHARJEE.
Researches on Ergot Production,
Botanical Laboratory, Presidency College,
Calcutta. June 7.

B Vitamins in African Fermented Foods

FERMENTED foods of various kinds constitute a common part of most African diets. Their importance has long been recognized by students of nutrition as a means of relieving the monotony of primitive diets based preponderantly on cereals. The work of Delf[1] and of Fox and Stone[2] has served to establish the antiscorbutic potency of one fermented food, kaffir-beer. During the past two years, we have been engaged in a study of the vitamin B contents of these foods, employing microbiological procedures for the determination of riboflavin[3] and nicotinic acid[4] and fluorimetric methods for thiamin[5] and riboflavin[6].

The foods so far investigated fall roughly into two groups depending on whether the fermentation which they have undergone is non-alcoholic or partly alcoholic. In the former category are the 'soured' foods such as *marewu*, thin soured maize-meal porridge, and similar forms of soured porridge; *leting*, a sour product of maize-meal and kaffir-corn malt fermentation; and *amaas*, soured milk. Kaffir-beer, a thin sweetish-sour gruel with an alcohol content approximately the same as ordinary beer, is the chief example of an alcoholic fermented food. Reference will also be made to 'small beers' and related products which fall into this group.

The average values for vitamin content given below, while they do not indicate the considerable variations which occur, convey some idea of the useful contribution to vitamin intake made by these foodstuffs. The fortuitous mixture of simultaneous lactic, acetic and other fermentations which constitute souring does not greatly affect the vitamin content of cooked cereals. Comparison of *marewu* with the original meal on a dry basis reveals a loss of thiamin of about 30 per cent (largely due to the preliminary boiling) and increases in riboflavin and nicotinic acid of about 40 per cent.

In common with others who have investigated sprouted seeds, we have found malted cereals such as maize, kaffir-corn and various millets to be lower in thiamin but considerably higher in riboflavin and nicotinic acid than the unsprouted grains. Consequently it is advantageous, from a pellagra-preventive point of view, to combine the sprouted with the unsprouted forms. Subsequent souring and straining, as in the preparation of *leting*, leads to an increase in all three B vitamins, particularly in riboflavin.

	Solids (per cent)	Vitamin content (μgm./ml.)		
		Thiamin	Riboflavin	Nicotinic acid
Marewu	9·0	0·19	0·16	2 32
Leting	9·5	0·30	0·34	3·64
Kaffir-beer	8·7	0·47	0·54	4·66
'Second' beer ..	5·0	0·22	0·46	2·81
'Third' beer	3·4	0·23	0·38	1·65
Amaas	12·1	0·40	1·75	1·55

In making *amaas* from milk, only the nicotinic acid content is substantially affected, being reduced to one third. In the winter milks so far studied, the low ascorbic acid, carotene and vitamin A levels are influenced adversely only by the storage necessary for souring.

The preparation of kaffir-beer involves the souring of a meal-malt mixture, as in *leting*; boiling and cooling; addition of extra malt and water; alcoholic fermentation; and straining, which results in the final beer. The values given above were obtained with beers prepared from kaffir-corn and maize meals with kaffir-corn malt. The ingredients vary greatly in different parts of Africa, as also do the details of the basic process. Yet on a dry basis we have found little difference between kaffir-beers brewed by Africans, by municipal breweries and by mine compounds. The yeasts (*Saccharomyces* and *Torulæ*[7]), *Mucor rouxii*[8] and other microflora which play their part in the final alcoholic fermentation bring about a remarkable synthesis of the three B vitamins which we have measured, and probably of the remainder of the B complex. Thus the final beer is not merely an aqueous-alcoholic extract of the vitamins present in the original meal and malt. On a dry basis it now contains roughly twice as much thiamin and nicotinic acid and three times as much riboflavin as the original ingredients.

When the beer has undergone its final straining, a considerable residue remains. In the African home it constitutes an inoculum from which, with the aid of more malt, a series of small beers and other fermented foods can be produced. In this way the synthetic activity of the beer culture is prolonged and the ensuing 'second' and 'third' beers, while lacking the body or flavour of the original beer, are almost equal to it in vitamin content. The watery 'third' beer may be consumed as such by women and children; or it may be used to ferment cooked cereals such as steamed maize bread, to which sugar has been added. Through such by-products of the kaffir-beer brew the nutritive benefit derived by the whole African family is greatly extended. Similar fermented foods arise from the *leting* process, but we have not as yet secured samples of these products.

Previous work in this laboratory[9] has shown that African cereals provide an adequate level of thiamin. It is the remainder of the B complex which must be taken care of in order to achieve vitamin balance. From this point of view, our findings reveal the value of fermented foods as dietary supplements.

In a detailed description to be published elsewhere, full acknowledgment will be made of the assistance afforded us in this investigation. Here we can only express our thanks to the Director of Pathology, South African Medical Corps, who enabled one of us (J. M. T.) to take part in this work.

Cultures of *Bacterium brunneum*

In connexion with some fundamental investigations on the removal of wool from sheepskins being carried out by the Council for Scientific and Industrial Research in Melbourne, we have made several endeavours to obtain a culture of *Bacterium brunneum*.

So far, we have been unable to locate a culture in any of the normal repositories such as the National Collection of Type Cultures, the American Type Culture Collection, the Pasteur Institute in Paris and the Bacteriology Department of the University of Pisa, and would like to ask the help of any of the readers of *Nature* who may know of or have a culture of the organism.

According to Bergey's "Manual", the organism was first isolated by Copeland[1] who called it *Bacillus brunneus*. Bergey *et al.* have transferred it to the genus *Flavobacterium* as *Flavobacterium brunneum* Bergey *et al.*

Assistance in this search will be greatly appreciated.

Unusual State at Birth of a Bat

During some recent observations on bats in Trinidad, B.W.I., an interesting variation from the normal state of young bats at birth was noticed. A pregnant specimen of *Artibeus planirostris trinitatis* K. And. (Phyllostomidæ) was under observation. Parturition occurred in the afternoon of March 9, 1945, and the young bat was closely examined within two hours and found to have its eyes open. As this seemed unusual, several further specimens of the same species were captured. These were all within a few days of parturition. The fœti were dissected out and examined, and it was found that these also had their eyes open.

This occurrence does not appear to have been recorded before for any family of bats. Dr. G. M. Allen[1], in his book on bats, summarized most of the published work on parturition and post-natal development of bats, but no mention of the above occurrence has been noted. Dr. H. B. Sherman, of the University of Florida, in a private communication, stated he knew of only one other case, which he observed recently occurring in *Tadarida cynocephala* (Molossidæ).

The Two-body Problem in Milne's Theory of Gravitation

In a recent communication[1], Dr. Camm has answered Schild's contention[2], that Milne's theory of the gravitational interaction of two massive particles in the field of the substratum is not Lorentz invariant and hence either invalid or else dependent on an arbitrary additional principle. Camm has shown that: (1) the consequences of Milne's theory are independent of any particular simultaneity convention, Lorentz-invariant or otherwise; and (2) the choice of such a convention, if Lorentz-invariant, is much more restricted than Schild supposes. While the particular convention, arbitrarily chosen by Schild, is shown to be invalid, Camm gives plausible reasons for adopting the convention,

$$t_1^2 - \mathbf{P}_1^2/c^2 = t_2^2 - \mathbf{P}_2^2/c^2,$$

linking the event $(t_1,\mathbf{P}_1)$ at the particle m_1 with the event $(t_2,\mathbf{P}_2)$ at the particle m_2. A conclusive reason, however, can be given for imposing this condition uniquely, as the following argument shows.

Using the t-scale, according to which the substratum is described as expanding uniformly from a point source, Milne[3] discovered a Lorentz-invariant form for the mutual gravitational potential of two superposed particles, m_1 and m_2, namely,

$$\chi = -\frac{m_1 m_2 c^2(t_1 t_2 - \mathbf{P}_1.\mathbf{P}_2/c^2)}{M_0\{(t_1 t_2 - \mathbf{P}_1.\mathbf{P}_2/c^2)^2 - (t_1^2 - \mathbf{P}_1^2/c^2)(t_2^2 - \mathbf{P}_2^2/c^2)\}^{1/2}},$$

where M_0 is the 'fictitious mass of the universe'[4], the numerical value of which is taken to be (in the present state of our knowledge) about $2{\cdot}4 \times 10^{55}$ gm. As χ is invariant for each fundamental observer of the quasi-continuous substratum, it follows that

$$\chi = -\frac{m_1 m_2 c^3 t_1}{M_0 |\mathbf{P}_1|},$$

where $(t_1,\mathbf{P}_1)$ are the co-ordinates assigned to an event at m_1 by the fundamental observer with whom m_2 coincides at the (local) epoch t_2; for this observer, of course, $\mathbf{P}_2 = 0$. Hence,

$$\chi = -\frac{m_1 m_2 c^3}{M_0 |\mathbf{P}_1/t_1|} = -\frac{m_1 m_2 c^2}{M_0 |\mathbf{V}_{12}/c|},$$

where $\mathbf{V}_{12}$ is the uniform velocity of relative recession of the fundamental observers with whom m_1 and m_2 are (momentarily) coincident, respectively.

Using the τ-scale, given by the clock-regraduation formula,

$$\tau = t_0 \log(t/t_0) + t_0,$$

it is easy to show[5] that the constant distance apart of m_1 and m_2 is λ_{12}, where

$$\tanh(\lambda_{12}/ct_0) = |\mathbf{V}_{12}/c|.$$

Hence, $$\chi = -\frac{m_1 m_2 c^2}{M_0 \tanh(\lambda_{12}/ct_0)}.$$

This formula was first given by Milne[6], but the present derivation appears to be more direct.

The outstanding feature of this form of the gravitational potential is its apparent independence of the local epochs, τ_1 (at m_1) and τ_2 (at m_2), and hence of any explicit relation between them.

The characteristic property of the substratum, in τ-time, is the co-existence of a public space and a public time, as in Newtonian physics. In examining any gravitational situation in the latter, it is usual to dissect the history of the system into a continuous set of maps recording 'world-wide' instants. In this way a meaning is given to the idea of conservation, for example, of energy. Similarly, in the gravitational situation considered here, the appropriate 'simultaneity condition' to impose, at least implicitly, is $\tau_2 = \tau_1$. This criterion is chosen freely, but the choice is unique and is not arbitrary. Reverting to t-time, it is easily seen[7] that, if $(t_1,\mathbf{P}_1)$ are the t-scale co-ordinates of the event τ_1 at m_1, and $(t_2,\mathbf{P}_2)$ those of the event τ_2 at m_2,

$$\tau_1 = \tfrac{1}{2}t_0 \log\left(\frac{t_1^2 - \mathbf{P}_1^2/c^2}{t_0^2}\right) + t_0,$$

and similarly for τ_2. Consequently, the relation, $\tau_2 = \tau_1$, tacitly assumed on the τ-scale, implies that, on the t-scale,

$$t_1^2 - \mathbf{P}_1^2/c^2 = t_2^2 - \mathbf{P}_2^2/c^2.$$

This is Camm's condition.

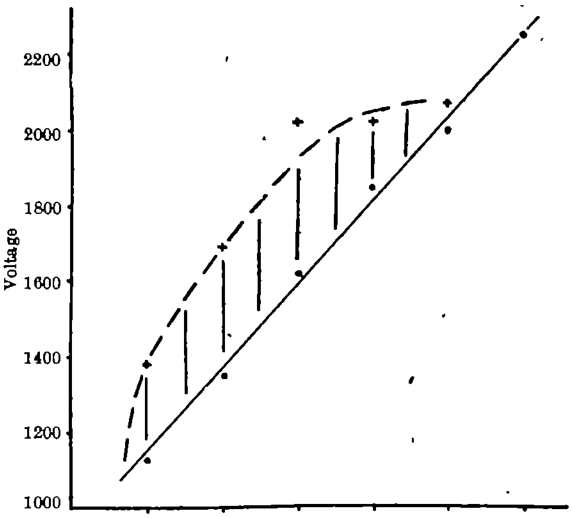
Effect of the Pressure of Alcohol Vapour on the Operation of the Fast Geiger-Müller Counter

As a result of the theoretical researches of Montgomery and Montgomery[1], Stever[2], Korff and Present[3], the operation of the fast Geiger-Müller counter is now very fully understood. In such a counter the discharge produced by a single ionizing particle is quenched by the following three processes: (*a*) The formation of a positive ion sheath which so reduces the field in the neighbourhood of the wire that further ionization by collision cannot take place. (*b*) The prevention of the emission of photo-electrons from the cathode by the rapid absorption of photons by the polyatomic vapour followed by the predissociation of the organic molecule. Processes (*a*) and (*b*) are of especial importance in the quenching of the initial discharge. (*c*) The prevention of the secondary emission of electrons from the cathode by positive ion bombardment by the predissociation of the organic molecule. Korff and Present have shown that the stopping of multiple discharges is due to process (*c*).

The role of the polyatomic vapour in the Geiger-Müller counter suggests that increasing the pressure of the vapour should improve the performance of the counter, since the efficiency of each quenching process would seem to be increased by increasing the quantity of vapour. A search through the literature showed that the references to the effect of the pressure of polyatomic vapour on the performance of the counter are very scanty. Only three observations[4,5,6] have been made, and the general trend of the results is to show that the efficiency of the quenching processes first increases and then decreases with increase in the pressure of the polyatomic vapour.

We have investigated this point by studying the variation in the length of the plateau of a Geiger-Müller counter of McCusker's design[7] with alcohol pressure for different pressures of argon. In order to avoid the possibility of the contamination of the cathode surface by the condensation of alcohol, all tests have been made at a temperature of 40° C. where the saturated vapour pressure of alcohol is 13 cm. mercury. The results, given in the accompanying table, show the effect of alcohol pressure on the starting potential and on the length of the plateau. The results for alcohol alone are plotted in the graph, the full line indicating the variation of starting potential and the broken line the onset of multiple discharges. The shaded portion is the region in which the counter is normally used to record ionizing particles.



STARTING POTENTIAL (FULL LINE) AND ONSET OF MULTIPLE DISCHARGE (BROKEN LINE) PLOTTED AGAINST PRESSURE OF ALCOHOL DIFFERENCES IN THE ORDINATES OF THE TWO CURVES REPRESENT PLATEAU-LENGTHS.

Two points emerge from the results: (1) the alcohol counter can be used only in a narrow range of alcohol pressures; and (2) the 'useful' pressure range is not affected to a great extent by the argon pressures used in this experiment; in fact, the argon acts merely as a 'filler' gas to increase the efficiency of the counter[5].

The graph brings out clearly that the variation in plateau-length is due to the difference in the variation of starting potential and of the production of multiple discharges. The variation of starting potential is seen to be almost linear, as might have been expected (Trost[4]).

Total pressure alcohol + argon (cm.)	Alcohol pressure (cm.)	Starting potential (volts)	Length of plateau (volts)
1	1	1130	250
2	2	1350	340
3	3	1620	400
4	4	1850	170
5	5	2000	70
6	6	2250	0
16	0		0
	0·5	1350	210
	2	1670	370
	2·5	1710	400
	3	1780	400
	4	2050	250
	5	2250	190
	6	2350	0
30	0		0
	2	2060	310
	3	2130	320
	4	2220	210
	4·5	2380	100
	6	2460	0

The curve showing the onset of multiple discharges as a function of pressure is determined by the efficiency of the quenching processes in preventing the rapid multiplication of electrons. Since this curve has the form shown, it is clear that the plateau will disappear as soon as the curve intersects the starting potential line. We would suggest that the decrease in the plateau is due to the failure of the quenching of secondary emission from the cathode by positive ion bombardment. The increase in starting potential causes the velocity of the positive ions to become so great that eventually there is a liberal emission of electrons from the cathode even at the starting potential.

Flow of Water Through Very Narrow Channels and Attempts to Measure Thermomechanical Effects in Water

We have recently experienced instances where, particularly under humid tropical conditions, evacuated and sealed-off apparatus has shown marked deterioration due to the appearance of water vapour inside the evacuated space. While the presence of water vapour can be easily and definitely established, it appears that the channels which allow this transference of water are impervious to air. This means that although the apparatus is, within the limits of our measurements, completely airtight, it nevertheless allows measurable amounts of water vapour to pass into the vacuum.

Considering it possible that this indicated the existence of some unusual properties of flow of water through exceedingly narrow channels (as occurs in the case of liquid helium[1]), we carried out some experiments on the flow of water through channels of the order of 10^{-5} cm. in width. Fig. 1 shows the simple apparatus used; at the centre of a horizontal capillary tube about 10 cm. long, a 'porous plug' of tightly tamped jewellers' rouge was arranged, with a continuous water column extending *through*, and on each side of, the plug. Pressures both above and below atmospheric could be applied at P.

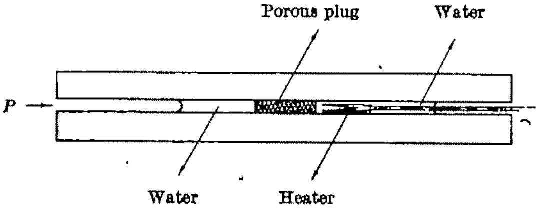

Fig. 1.

By observing the rouge particles under a high-power microscope, the average particle size was reckoned to be about 10^{-4} cm., and the average width of channel between the particles was about $1 \cdot 5 \times 10^{-5}$ cm. By observing the rate of flow of dry air through the plug *before* the introduction of the water column, and using the known value for the viscosity of air, we were able to obtain a reasonable check on both the number of channels through the plug and their average width. These figures were afterwards used to obtain a value for the viscosity of water when flowing through the porous plug.

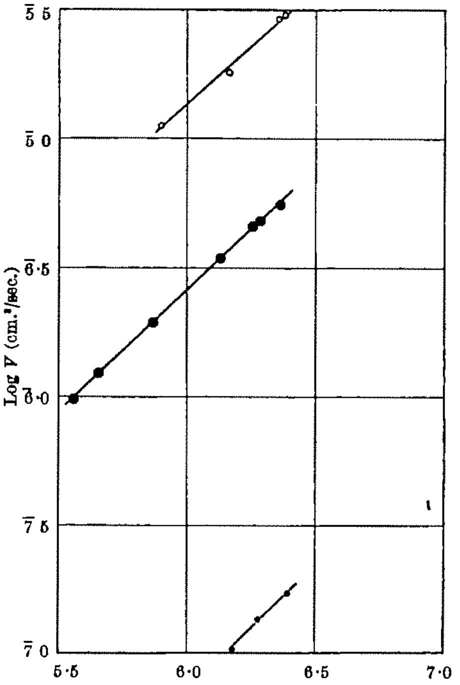

Fig. 2. Average channel width: o, 2×10^{-5} cm.; ●, $1 \cdot 5 \times 10^{-5}$ cm.; •, $0 \cdot 7 \times 10^{-5}$ cm.

Fig. 2 shows typical results for flow of water through several different porous plugs. The flow was purely laminar ($d \log V/d \log P \doteqdot 1$), even up to pressures of 3 atmospheres; but the actual value of viscosity appeared to be some five to ten times larger than for flow through smooth capillaries. In view of the uncertainty in the channel width, this is probably within the limits of error of our measurements; but there is clearly no evidence of anything in the nature of 'superfluidity'. Flow was observed through plugs of various materials (for example, rouge, French chalk, fine carborundum) and all gave practically identical results.

Thus the flow of water through channels of this width appears to follow the usual hydrodynamic laws; but, after the water had been forced clear of one side of the plug, it was then found impossible to drive any air through the plug, even with pressures up to 3 atmospheres applied at P. Water could, however, continue to be drawn backwards or forwards through the plug. Even when the water was totally removed from the capillary, the plug still remained vacuum tight, the flow of air being at any rate less than one ten-thousandth that observed when the plug was dry.

The possibility of the existence of a 'thermomechanical effect' in water (as occurs in liquid helium[2]) was also investigated, by inserting a heater on one side of the plug as shown in Fig. 1, and noting whether the rate of flow was altered when a heat input was applied. Although distinct changes in the rate of flow of the water were observed for quite small heat inputs (up to ¼ watt), it was clear that these changes were not to be associated with a thermomechanical effect. Two reasons lead us to this conclusion, namely, the facts that the rate of flow was *increased* whether the excess pressure P was above or below atmospheric, and that when P was zero no flow could be detected. The change in rate of flow is almost certainly due merely to the decrease in viscosity resulting from a rise in temperature when the heat input is applied. An attempt to observe a thermomechanical effect directly, with apparatus similar to that used in the quantitative measurements on helium[2], also gave a negative result. Landau[3] has stated that a thermomechanical effect in water is to be expected; but from our results it is clear that any such effect, if it exists, must certainly be less than one ten-thousandth of that observed in helium.

We must conclude that the flow of water through very narrow channels of the order of 10^{-5} cm. in width exhibits no very unusual features. The leakage of water vapour which is observed to occur into evacuated apparatus through such narrow channels must therefore be presumed to be due to surface tension action alone. Further, so long as the apparatus is maintained in a normally humid atmosphere, it will not be possible to detect any air leakage unless excess pressures are used exceeding that due to the surface tension, which can, of course, in channels of this width, reach very high values.

Near Ultra-Violet Emission Bands of Benzene

IN the course of a study of the high-frequency discharge in benzene vapour, a set of bands in the spectral region 3000–2475 A. is obtained using oscillations in the frequency range 1765–1200 kc./sec. to excite the flowing vapour of benzene (pressure ~ 0·1 mm. mercury). These oscillations were produced in a modified Hartley circuit using a Mullard *PM4DX* valve. A Hilger medium quartz spectrograph was used as the resolving instrument to photograph the spectrum. The bands, which are degraded towards longer wave-lengths, occur in several distinct groups, six such being obtained in the present experiments. Measurements of the wave-lengths of the band heads show that they are identical with the bands obtained in the Tesla discharge in benzene vapour[1,2].

It has been possible to analyse most of the bands observed into five series designated as *A*, *B*, *C*, *D* and *F*, in all comprising about 76 band heads, in accordance with the nomenclature adopted by Sponer *et al.*[3], in their analysis of the near ultra-violet absorption bands of benzene. It may be recalled that these absorption bands of benzene are, according to Sklar[4], due to the forbidden electronic transition ${}^1A_{1g} \rightarrow {}^1B_{2u}$ which can only be made possible in the presence of a superposed non-totally symmetrical vibration of the type ε_g^+. In agreement with this deduction, all of these five series in emission, except the *F* series, involve the (606 cm.$^{-1}$) ε_g^+ vibration, either in the final state or in the initial state where its frequency falls down to 520 cm.$^{-1}$ exactly as in absorption or fluorescence spectra. The present data on the *F* series, however, are better represented if a frequency of 1610 cm.$^{-1}$ instead of 1596 cm.$^{-1}$ is assumed for the second ε_g^+ vibration which is also present in the ground state. The average discrepancy between observed and calculated values is 5 cm.$^{-1}$, which is equivalent to about 0·4 A. in this region and is within the limits of experimental error. About twenty band heads the intensity of which is low do not afford unambiguous classification. They fit in fairly well as members of one or other of the above series, involving frequencies both in the excited and the ground states; but it is also possible that they may involve some other new series altogether.

Whereas in absorption the positive members of the various series, that is, those involving frequencies of the excited state, are naturally predominant, in high-pressure fluorescence it is the negative members involving vibration frequencies of the ground state which form the bulk of the spectrum. Indeed, a rearrangement of the data of Ingold and Wilson[5] on the fluorescence spectrum of benzene clearly shows this expected difference between absorption and high-pressure fluorescence. The emission spectrum, which ought to contain both types of members of the series and hence present a much more complicated structure is, however, surprisingly simple. This is due to the circumstance that although both negative and positive members of the series are present, they are not loaded with more than 3 or 4 quanta of 160 cm.$^{-1}$, which is the difference between $(\alpha^1_{2g})''$ (400) and $(\alpha^1_{2g})'$ (240) non-totally symmetrical frequency. In contrast to this, it may be noted that most of the series observed in fluorescence are loaded with high quanta (in some cases up to 26) of this difference frequency.

The intensity distribution in each series of bands is roughly the same as that observed in the fluorescence spectrum, namely, an almost regular decrease with increasing quantum numbers of vibration in each series. The intensity of the various series is, however, in the following order: *B*, *F*, *D*, *A* and *C*. This may be contrasted with the intensity of the fluorescence series, which from the data of Ingold and Wilson gives the following order: *C*, *A*, *B*, *E* and *D*.

This analysis shows that the bands observed are, as in fluorescence, to be attributed to the electronic transition ${}^1B_{2u} \rightarrow {}^1A_{1g}$ in the benzene molecule.

The 'Green Flash' at Sunset with a Near Horizon

THE observation of the 'green flash' with a near horizon, presumably at Harrow, recorded by Mr. D. R. Barber in *Nature* of August 4, p. 146, recalls one of which I gave an account in the *Meteorological Magazine* of October 1926. In this case the artificial 'horizon' was a building some miles off, and the colour of the flash was "a smoky white with a faint tinge of green". Mr. Barber also comments on the small saturation of the colours which he observed; it is possible that this is due, not to the nearness of the 'horizon', but to the smoky atmosphere of London.

OXIDATION AND REDUCTION IN CHEMISTRY

By Prof. J. KENNER, F.R.S.
College of Technology, Manchester

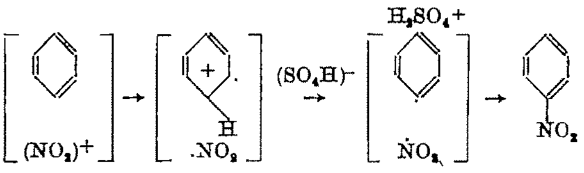
THE conjunction in *Nature* of July 14 of the article by Dr. D. H. Hey entitled "The New Organic Chemistry" with the correspondence on olefinic-α-halogenation prompts me to offer some comments and an intimation of various relevant results recently obtained in my laboratory.

The conclusion from Gomberg and Bachmann's results that "the laws of aromatic substitution did not hold", and the view that "free radicals were involved" in these and the various reactions studied by Hey and Waters are not warranted by the facts. The absence of *meta*-derivatives from the products of reaction is clearly indicative of some regularity of the substitution process and we therefore seek correlation with recognized processes. This reveals an apparently paradoxical correspondence with what has been termed cationoid substitution of benzene and its homologues on one hand, and with what is usually called anionoid substitution of nitrobenzene on the other. Further, however, the same applies to mercuration[1], and there is also agreement between the results of mercuration[2], and of coupling in presence of cupric salts[3], in the case of α-β-unsaturated esters and carbonyl compounds. We are thus confronted with two concordant instances of a paradox, which must be resolved instead of being merely relegated to a "New Organic Chemistry".

It has for some considerable time appeared to me to be a capital defect of the usual presentations of organic reactivity that, with so much that is cogent, there is insufficient expression, and so, frequently, insufficient realization, of the essential community of all chemical reactions. Considerations of history, simplicity and ultimate value all suggest that this expression should be, as, indeed, physical chemists have recognized, in terms of oxidation and reduction. It is for this reason that work in my laboratory has for some time been directed to the relationship between processes of substitution and those of oxidation[4]. This matter is, for example, only introduced towards the end of Ingold's monograph on "Organic Reactions"[5], and receives no specific attention in an exposition by Sir Robert Robinson[6]. Although, in his most recent discussion[7], an earlier suggestion by Jacobson[8] provoked attention to the matter, this did not suffice to obviate a conclusion endorsing the views of Hey and his associates. Indeed the currency which they have so long enjoyed is a testimony to the reality of the defect to which I point.

For these reasons, I prefer, even at the risk of some apparent retrogression[9], to adopt a device of approximation, representing organic reactions as a sequence of steps, involving the full electron transfer of oxidation and reduction processes, in which, however, the reactants remain "within the sphere of each other's action"[10], and to indicate this by the bracket notation conventional for such purposes among organic chemists.

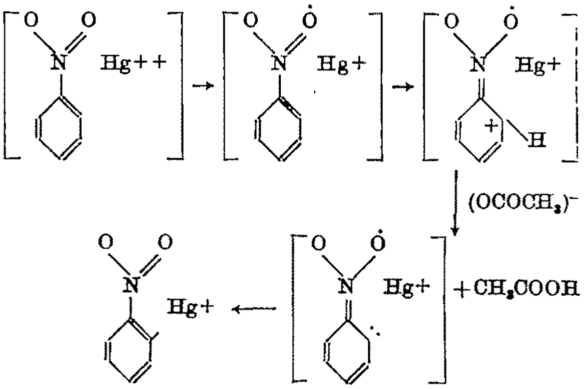
On this basis I formulate the nitration of benzene as follows:



I II

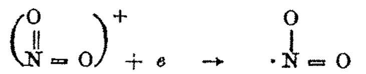
The initial change involves transference of a π-electron, while the transition from (I) to (II) by loss of a proton to the surrounding medium by means of the hydrogen bond mechanism is determined by the tendency to restore the aromatic condition and neutrality of the nucleus.

While the mode of application of this to mercuration is obvious, it illustrates the force of the suggestion[11] "that radicals, rather than ions, are produced more frequently in organic reactions than is usually realized". Also, it at once becomes apparent that, in the Bamberger and related reactions, with the systematic exploitation of which Hey and his co-workers have been concerned, the radical is not, as they have supposed, pre-existent or free, but generated as a transient phase during the reaction. Abstraction of an electron from the molecule of nitrobenzene will occur at an oxygen atom, and in the case of mercuric ion the sequence of changes can be expressed as follows:



The limitation of mercuration to the *ortho*-position is presumably due to retention of the mercurous ion (negatively charged by comparison with the mercuric state) in close proximity in the transition complex to the nitro group. A neutral phenyl radical has more freedom, so that *para*-arylation ensues.

Considerations of space preclude treatment here of the various issues arising from this discussion of the Bamberger and related reactions; but some perspective view of the matter is desirable at this point. Thus, since this hitherto unrecognized mode of *ortho-para* substitution arises from the variable degree of oxidation of the substituting agent, it should occur in other instances of this type. Accordingly, the ordinary *meta*-directed nitrations are accompanied by formation of notable amounts of *ortho*-derivative:

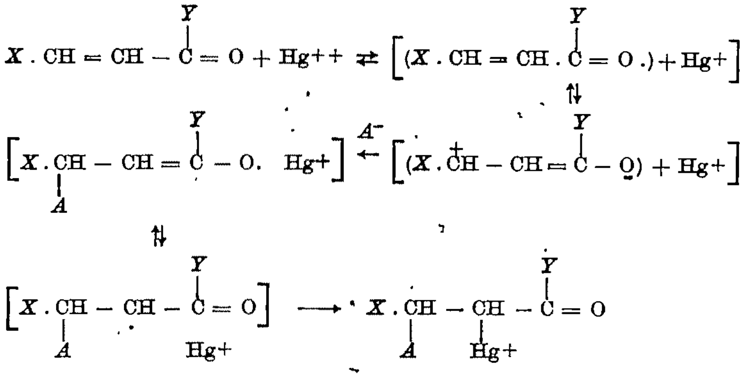


$$\left(\begin{array}{l}O\\ \|\\ N=O\end{array}\right)^{+} + e \rightarrow \begin{array}{l}\;\;O\\ \;\;|\\ \cdot N=O\end{array}$$

and to a greater extent with greater ease of surrender of an electron by the directive group. Similarly, as much as thirty per cent of *para*-disulphonation of benzene occurs at 183°[12].

The reaction of nitro-compounds with hydroxyl[13], cyanide[14], or fluorenyl[15] ions represents a variant of this mode of *ortho-para* substitution, in which both a molecule of the nitro-compound and the ion suffer loss of an electron to another agent, and to which similar considerations in regard to *ortho-* or *para*-substitution are applicable.

Whereas such substitution of nitrobenzene arises in general from activation of the nitro group by an agent which later becomes a substituent, ordinary *meta*-substitution, so far as it is due to activation[9], depends on that of an external agent, for example, by hydrogen bond formation. *Meta*-substitution is thus related to α-activation of carbonyl compounds by acids. If, however, an αβ-unsaturated carbonyl derivative be activated by mercuric ion, we have the following changes:



Although this case is closely related to the mercuration of nitrobenzene, there is here no need for proton extrusion, since the radical ion can achieve neutrality by accepting an anion A^- from the surrounding medium. Consequently the relative sites of mercuration are different in the two cases. Initial activation by cupric ion would generate cuprous ion which, as Waters has recognized, will in turn liberate from diazonium ion phenyl radical for arylation corresponding to the mercuration just discussed.

We need thus only speak of the 'new' organic chemistry in the sense that we enlarge the present relatively limited outlook to one exhibiting more explicit recognition of the relation of chemical reaction to processes of oxidation and reduction. Indeed, the formulation of chemistry in general needs a similar revision. Thus, we have as examples from inorganic chemistry related to those above, the substitutive mercuration of ammonia in the formation of Nessler's reagent, and the colour of those metallic compounds which do not contain coloured cations. The colour of mercuric oxide, for example, is presumably due to a relationship in its lattice which we may represent

$$Hg^{\cdot\cdot}O'' \rightleftharpoons Hg^{\cdot}O'.$$

A kinetic study of the nitrosation of dimethylaniline, carried out in conjunction with Dr. G. Baddeley and Mr. D. M. Lever, having revealed a similar accelerative influence of chloride ions to that observed in the case of diazotization, we have shown that a nitrosating reagent, with $[H^\cdot]$, $[Cl']$ and $[HNO_2]$ respectively 0·2, 1·9 and 0·1 molar, slowly dissolves metallic gold at the ordinary temperature, while solutions of benzene, ethyl benzene and tetralin in glacial acetic acid saturated with hydrogen chloride and containing a molar concentration of nitrous acid at 25° furnish small yields of chlorobenzene, 4-chloroethylbenzene and a mixture of *ac-* and *ar*-chloro-derivatives respectively. In other words, we have in the reagent

$$HNO_2 + H^\cdot + Cl' \rightleftharpoons H_2O + NO + Cl,$$

corresponding to the familiar reaction with iodide ion, and the acceleration noted above is due to atomic chlorine or to nitrosyl chloride, according as one regards the latter[11].

A kinetic study with Dr. G. Baddeley has shown that the rate of formation of 4 : 4′-diethoxy-1 : 1′-dinaphthyl from α-ethoxynaphthalene in presence of nitrobenzene and aluminium chloride is proportional to the concentration of the ethoxy-derivative. It thus involves the corresponding radical[11]. It is illustrative of the theme developed at the outset of this note that the course of the reaction is essentially that of benzene substitution as formulated above.

It seems to have been overlooked that olefinic α-oxidation was established so far back as 1894 when Wagner demonstrated the structure of sobrerol.

Studying the use of tertiary butylhypochlorite as a chlorinating agent, Dr. R. F. Garwood and I have shown it to (*a*) attack carbonyl compounds instantly, especially in presence of a trace of aluminium chloride, boron trifluoride, etc., forming, for example, mono- and di-chloroethyl malonates from ethyl malonate; (*b*) furnish a 65 per cent yield of Δ^2 *cyclo-hexenyl* chloride from cyclohexene under Ziegler's chlorination conditions. Also, independently following this up, Dr. Garwood has demonstrated the efficiency of this reagent in presence of benzoyl peroxide in chlorinating toluene, ethyl benzene, *p*-bromotoluene and *cyclo*-hexane to benzyl chloride, α-phenylethyl chloride, *para*-bromobenzyl chloride, and *cyclo*hexyl chloride respectively. Further, in contrast to the experience of Kharasch and Brown, using sulphuryl chloride and benzoyl peroxide, even *para*-nitrotoluene furnished some *para*-nitrobenzyl chloride.

It is obvious that fuller treatment of these various matters is required, and it is hoped to provide these in due course.

GAS RESEARCH BOARD

THE Gas Research Board—now responsible for the research activities of the British gas industry—has issued its fifth annual report (Gas Research Board, 1 Grosvenor Place, London, S.W.1), covering the session ending June 30, 1944. With the end of hostilities in Europe it has become possible to disclose some of the war-time activities.

Work on the gasification of coal in hydrogen under pressure had, by that time, passed from the laboratory into the works as a result of the installation of a small plant in the Bournemouth gasworks. In the initial stages a semi-coke, heated to 600° C., was treated with hydrogen under 50 atmospheres pressure. Under these conditions, gasification partly by liberation of volatile matter and partly by reaction of hydrogen with carbon takes place with great rapidity, for the formation of methane is an exothermic reaction. Another approach to the production of methane from coal is the synthesis from mixtures of carbon monoxide and hydrogen. Synthesis of liquid hydrocarbons is better known, but by choice of catalyst and conditions methane can also be obtained. The most important of the conditions is the almost complete removal of organic sulphur from the gas by processes which require very stable catalysts. Results of high promise have been obtained and suggest that fuel gas may soon be distributed almost free from sulphur.

All this work aims at the preparation of a fuel gas without the limitation of starting from high-class coking coal, rather indeed from any coal. This achievement will almost certainly be accompanied by the production of gas from sulphur.

In recent years it has been recognized that although heat is transferred by convection and radiation, the differentiation of the two may be important. In certain operations, especially those involving drying, radiation may prove more effective than convection. Effectiveness may be influenced by the quality not only of the source of radiation but also by that of the surface receiving the radiation. The report shows that the Gas Research Board is actively engaged in this field because gas-heated surfaces are specially effective for radiant heating, and this promises great industrial application.

Another branch of the Board's activities involves the separation by refrigeration of coal gas into its constituent gases, whereby advantage can be gained from the special properties of each.

The report shows that the Board, in spite of war-time difficulties, is making rapid progress in the development of new techniques for the manufacture and use of gaseous fuel.

FREQUENCY OF EARTHQUAKES IN CALIFORNIA

ACCORDING to Gutenberg and Richter, the southern California area, including the Owens Valley, has about one half of one per cent of the seismic activity of the globe ("Frequency of Earthquakes in California." By B. Gutenberg and C. F. Richter. *Bull. Seis. Soc. Amer.*, 34, No. 4, 185; 1944). This conclusion is arrived at by considering statistically up-to-date information concerning earthquakes, employing the instrumental magnitude scale.

The magnitude M of an earthquake was originally defined as proportional to the logarithm of the maximum trace amplitude on the seismogram of a standard torsion seismometer distant 100 km. from the epicentre, and having a normal shallow depth. The magnitude scale is chosen to make $M = 0$ correspond to the smallest instrumentally recorded shocks. It is found that $M = 2$ corresponds to the smallest shocks ordinarily reported felt, $M = 4{\cdot}5$ causes slight damage, $M = 6$ earthquakes are moderately destructive, and $M = 8{\cdot}5$ corresponds to the largest recorded shocks.

Since 1921, the following shocks in the California–Nevada region have had magnitude 7 or greater: Jan. 31, 1922 (7·3), off the north coast; Jan. 22, 1923 (7·1), off the north coast; Nov. 4, 1927 (7·0), off Point Arguello; Dec. 20, 1932 (7·3), west-central Nevada; Dec. 31, 1934 (7·0), south of the Imperial Valley. In the present century, two shocks in the same region have exceeded magnitude 7·5: April 18, 1906 (8·25), central California; Oct. 2, 1915 (7·75), north-central Nevada.

This gives the California–Nevada region about 90 per cent of the seismic activity of the United States.

According to the authors, the expected occurrence of about four great earthquakes per century in the California region by no means excludes the possibility that double that number might occur in a given century, or that a whole century might pass without even one. Further, the events are not strictly independent. A great shock, such as that of 1906, represents a regional release of strain; after the immediate aftershocks have subsided, it may be expected to be followed by a period of abnormal quiet, as is probably now the condition in central California. It is worth noting that great shocks are to be looked for only in association with the major active faults and structures, such as the San Andreas fault zone and the trough of the Owens Valley. The other faults and active structures are characterized at most by moderately destructive earthquakes like those at Santa Barbara and Long Beach.

THE STONE AGE IN EAST AFRICA

IMMEDIATELY before the War, industries belonging to a so-called Tumbian culture were being recognized at many sites in eastern and western Africa. First noticed by Dr. X. Stainer in the Congo, industries of similar types were soon being identified in many other areas. Dr. Menghin and T. P. O'Brien (in his book on the prehistory of Uganda) went so far as to suggest that the Tumbian culture was derived directly from that of the *coups de poing* makers, that it could be described as a sort of Acheulean gone to seed. Prof. H. Breuil, however, in a recent study of Dr. Cabu's finds, denies the existence of the Tumbian as a distinct culture, and he and Prof. van Riet Lowe suggest that the industries represent only a variation of the Sangoan culture of Uganda with strong Fauresmith affinities (*Trans. Roy. Soc. of South Africa*, 30, pt. ii; 1944).

Dr. Leakey and Archdeacon Owen have now entered the ring, and in the first Occasional Paper of the Coryndon Memorial Museum, entitled "A Contribution to the Study of the Tumbian Culture in East Africa", they unequivocally uphold its status as a culture. Owen and Leakey's publication deals mainly with a series of sites, chiefly from the Kavirondo area, where industries belonging to various stages of this debatable culture have been discovered. There are several pages of illustrations. In conclusion, there is a general discussion on certain aspects of the Stone Age in Kenya, followed by an appendix, where Breuil and Lowe's work, quoted above, is cited, and the conclusions there set out denied.

As a personal opinion I can only add that every so-called Tumbian assemblage of implements which I have seen has appeared to contain several elements and to have been a mixture of the relics of more than one culture. Certain types do certainly seem to be derived from a *coup-de-poing* prototype. There is no reason to deny the possibility of a late survival of the early palæolithic cultures in parts of Africa where the sharp division lines resulting from the several glacial maxima are absent. That a part of the so-called Tumbian is, as the authors claim, something new to us and derivative from the Acheulean would seem to be quite possible; but that the industries discussed contain elements from other cultures and that therefore a pure Tumbian industry has yet to be isolated is also more than likely.

M. C. BURKITT.

FORTHCOMING EVENTS

Saturday, September 22

BRITISH PSYCHOLOGICAL SOCIETY (at Tavistock House, Tavistock Square, London, W.C.1), at 2.30 p.m.—Mr. E. G. Chambers: "Statistical Psychology, a Plea for Scientific Method"; Mr. Ranyard West: "The Contribution of Psychology to Politics".

Monday, September 24

ASSOCIATION OF AUSTRIAN ENGINEERS, CHEMISTS AND SCIENTIFIC WORKERS IN GREAT BRITAIN (at the Austrian Centre, Swiss Cottage, 69 Greencroft Gardens, London, N.W.6), at 7.30 p.m.—Dr. M. D. H. Strauss: "The Physical Basis of the Atom Bomb".

Tuesday, September 25

ROYAL PHOTOGRAPHIC SOCIETY, SCIENTIFIC AND TECHNICAL GROUP (at 16 Prince's Gate, London, S.W.7), at 6 p.m.—Dr. G. B. Harrison: "How it Works in Photography", No. 1. "The 'Light and Shade' of Image Formation".

QUEKETT MICROSCOPICAL CLUB (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Conversation and the Exhibition of Specimens.

Thursday, September 27—Friday, September 28

FARADAY SOCIETY (at University College, Gower Street, London, W.C.1).—General Discussion on "Oxidation".
Thursday, September 27, at 11 a.m.
Friday, September 28, at 10.30 a.m.

Friday, September 28

BIOCHEMICAL SOCIETY (in the Human Nutrition Research Unit of the Medical Research Council, National Hospital for Diseases of the Nervous System, Queen Square, London, W.C.1), at 11 a.m.—Scientific Papers and Demonstrations.

PHYSICAL SOCIETY, OPTICAL GROUP (Department of Physics Imperial College, London, S.W.7), at 3.15 p.m.—Mr. E. Wilfred Taylor: "Evolution of the Dividing Engine"; at 5 p.m.—a film entitled "Motion-picture Records of the Whole Sky" will be shown.

INSTITUTE OF WELDING, EAST SCOTLAND BRANCH (at the Heriot-Watt College, Chambers Street, Edinburgh), at 7.30 p.m.—Mr. A. Stephenson and Mr. D. Llewellyn: "Welding: Past, Present and Future".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

AGRICULTURAL ASSISTANT EDUCATION OFFICER—The Chief Education Officer, County Education Office, Stracey Road, Norwich, endorsed 'Agricultural Assistant Education Officer' (September 29).

SENIOR ENGINEERING ASSISTANT—The Surveyor, Hebburn Urban District Council Offices, Argyle Street, Hebburn (September 29).

LABORATORY TECHNICIAN—The Medical Superintendent, Birmingham Mental Hospital, Winson Green, Birmingham (October 1).

CHAIR OF CHEMICAL ENGINEERING tenable at the Imperial College of Science and Technology—The Academic Registrar, University of London, Richmond College, Richmond, Surrey (October 3).

ENGINEERS (temporary staff) by the Government of Nigeria for the Public Works Department—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting E.1899.A (October 5).

LECTURER IN ENGINEERING SUBJECTS in the Royal Aircraft Establishment Technical School, Farnborough, Hants.—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting C.2641.A (October 5).

SUPERINTENDENT (with qualifications in chemical technology and chemical engineering research applied to explosives) in a Government Research Establishment—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting F.3886.A (October 5).

GEOLOGIST by the Government of Iraq—The Ministry of Labour and National Service, A.9, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting F.4826.A (October 5).

PHYSICISTS (2) for a Petroleum Research Station near London—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting A.1028/4.XA (October 6).

LECTURER IN CHEMICAL ENGINEERING in the Department of Oil Engineering and Refining—The Secretary, The University, Edmund Street, Birmingham 3 (October 8).

TECHNICAL ASSISTANT (Chemist) in the Sewage Disposal Department—The Town Clerk, Guildhall, Nottingham (October 15).

ASSISTANT LECTURER AND DEMONSTRATOR IN BOTANY—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (October 21).

THIRD LECTURER IN BACTERIOLOGY and ASSISTANT BACTERIOLOGIST in the Public Health Laboratory—The Secretary, The University, Birmingham, 3 (October 31).

READERSHIP IN PUBLIC HEALTH tenable at the London School of Hygiene and Tropical Medicine—The Academic Registrar, University of London, Richmond College, Richmond, Surrey (January 1).

SENIOR SCIENCE MASTER in the King Edward VII School—The Director of Education, Education Office, Leopold Street, Sheffield, 1.

UNIVERSITY ASSISTANT IN THE DEPARTMENT OF NATURAL HISTORY in the United College, St. Andrews—The Secretary, The University, St. Andrews.

LABORATORY ASSISTANT IN THE DIVISION OF HISTOLOGY—The Bursar, Royal Veterinary College, Camden Town, London, N.W.1.

TECHNICAL ADVISORY OFFICER—The Executive Officer, Shropshire War Agricultural Executive Committee, County Buildings, Shrewsbury.

COLONIAL UNIVERSITIES AND THEIR FUNCTIONS*

IN the second part of its report, the Asquith Commission surveys in considerable detail the special problems involved in the provision of professional and vocational courses in the universities and university colleges, and the needs of medicine, agriculture, veterinary training, law, engineering, and the training of teachers; and the medium of instruction and linguistic training are discussed in a series of chapters with appropriate recommendations. These include, for example, the establishment of medical schools to serve those Colonial regions which do not now possess them, and refer to the fruitful opportunities for research which medicine presents in the Colonies; but like the Goodenough Inter-Departmental Committee on medical schools in Britain, the Commission recommends that medical schools should be integral parts of universities, and that full participation in the life of universities and close association with those following other branches of learning will provide the greatest stimulus to teachers and encourage medical students to develop those qualities of mind and character which go to the making of good medical practitioners. There is sage counsel on the functions of universities and university colleges in agricultural education, and a clear conception of the contribution of the university to agricultural education through its extra-mural activities, the importance of which is also well brought out in the first part of the report. The exceptional importance of veterinary training is recognized, and also the value and limitations of civil engineering, instruction in which up to B.Sc. standard in Colonial universities or colleges is recommended, although it may for a time be difficult to provide in the Colonies either the practical experience of good engineering work or facilities for fundamental research.

On the training of teachers, the Commission recognizes that, while it may for many years be impracticable to require that all teachers in the secondary schools shall be graduates, teachers in the higher and middle forms should be graduates. The university should concern itself primarily with the training of intending teachers who have already graduated, and with other teachers required for secondary schools. Recommendations as to the type of instruction are included; the department of education should be under a professor, and should be a centre of research in the many problems of school education in Colonial conditions; while in organizing the department of social sciences in the faculty of arts, the university should provide for research into linguistic problems to be pursued in close association with the departments of anthropological and sociological studies.

The third part of the Asquith Commission's report summarizes the report of the West Indies Committee and endorses its recommendations. As already noted, the chief of these is the establishment of a single University of the West Indies at the earliest possible date. The first step should be the foundation of a university college, which, in order to establish its academic standards and win public confidence and esteem, should work for the most part for the external degrees of a university of repute. After a short period of apprenticeship, the college would obtain a charter and begin its autonomous life, providing initially for some 400–500 students, men and women. The Committee insists that the university should be a single centralized institution and entirely residential. Three years would be the usual period of residence and study to qualify for a degree, and the university should teach the basic subjects appropriate to degrees in arts and science, and should include a faculty of medicine. Provision should be made to enable as many students as possible to pursue in Britain or elsewhere such further professional and postgraduate training as may not be available in their own university. The university should also be the headquarters of an important department of extra-mural studies through which its influence would be projected into all the West Indian Colonies. The Secretary of State for the Colonies has just announced that the proposal has his full support, and that he is prepared to consider making a grant under the Colonial Development and Welfare Act towards building costs.

---

* Continued from p. 347.

The arguments which lead to these findings reflect the whole spirit of the Asquith Report, with which the West Indies Committee report makes a coherent whole. The Committee was impressed with the strong evidence of the deficiency of technical education and the urgent need for skilled workers in nearly all branches of industry. There was a remarkable degree of local support for a unified institution, and the choice of Jamaica as site was reached last but independently by all members of the Committee. The same high conception of an educational system as a dynamic system inspires its report. The university is regarded as not simply enriching the fields of higher learning, but also influencing deeply the whole system of education by returning into its service, among others, secondary school and training college teachers, and in many intangible and indirect ways affecting the attitude of the community as a whole towards education and learning. Further, the essence of a university is that it should be a community of men and women pursuing a wide range of studies, humane and scientific, so that a continuous process of mutual education and intellectual broadening goes on, outside as well as inside the lecture rooms and laboratories. The Committee's recommendations spring from its faith in the positive contribution that a university could make to all the Caribbean territories, which are now for the first time being brought into a co-operative relationship. The Committee believes that a university should be the intellectual centre of a region to which its own graduates may look for encouragement and refreshment, and which may also be a meeting-ground for all those pursuing knowledge at the higher levels. Finally, it insists that the university should be a centre for research as well as teaching, and envisages the university as the main centre of research into the physical and social problems of the whole region. Indeed, the chapter on research, though shorter than that in the Asquith Commission's report, is nevertheless no less worthy of careful study.

Space does not permit further quotation from this discerning and admirably presented report, and reference can be made only to one other point. The problem of training in medicine is beset with difficulties as regards the immediate future, for the establishment of a complete faculty of medicine located at the seat of the university in Jamaica and working in association with the Kingston General Hospital can become operative only when the complete university scheme comes into existence. The need is urgent, and on investigating the possibility of providing a medical course in the West Indies which would function as an emergency measure until the university comes into full operation, the Committee recommends the adoption with some minor modification of Sir Rupert Briercliffe's scheme for the establishment of a temporary medical school in Trinidad, working in association with McGill University, Montreal.

The report of the Elliot Commission is the longest of the three reports; but as already indicated, it is not unanimous, nor, save perhaps in passages of the minority report, is it inspired by quite the same clear conception of the university ideal. There is an able survey of the general and of the educational background of West Africa and a lucid description of the present institutions for higher education there; but in their discussion of the future development of higher education, of the supply and training of teachers, of medical and health education, including dentistry, of agriculture, forestry, and animal health, and of technical education, the majority seem sometimes to have lost sight of general principles and objectives in a mass of local detail. The general case for the creation of universities in the Colonial areas argued by the Asquith Commission is indeed fully endorsed. Moreover, the proposals of the majority to develop a new university college at Ibadan in Nigeria (including faculties of arts and science, with schools of medicine, agriculture, forestry and animal health) to serve the whole of West Africa; a development of Achimota College in the Gold Coast (including faculties of arts and science, and an institute of education) and a reorganization, on a new site, of Fourah Bay College, which will also serve the Gambia (to include courses in arts and science up to the intermediate level and a teacher training course) are supported by the three West African members of the Commission. These university colleges are themselves to be centres of research and to collaborate closely with research organizations in West Africa, and the guidance of the Inter-University Council for Higher Education in the Colonies proposed by the Asquith Commission is welcomed. Higher education is here also considered as an integral part of a complete educational system. But the minority report appears to be argued more closely from first principles. This report rejects the majority proposals as likely to impede the earlier provision of a full range of university facilities in the West African territories. This aim requires that any future university must have all the necessary material facilities planned and provided without delay, with adequate staff of high calibre. The recognition outside West Africa of any university institution will depend not only on the quality of the teaching given to its students but equally on its research achievements. The minority also insist that no university institution can fulfil its purposes unless it is comprehensive in scope; students of a variety of faculties must work together in a single institution and share a corporate life; and lastly, no college aiming at university status can progress with any speed towards its goal unless the students entering it are adequate both in numbers and in equipment for university study.

It is on these principles, and particularly on the incapacity of the areas to supply an adequate flow of students able to pursue successfully degree courses within the period normally allocated to these courses in universities of Great Britain, that the minority dissent from the recommendations of the majority, although with much of the majority report they are in agreement. They are deeply impressed with the intense need for the development of studies in arts and science to the same level side by side. In their view, every endeavour should be made to build up a first-class scientific centre by concentrating scientific development at the West African University College at Ibadan, where co-operation with those working in medicine, animal health, agriculture and forestry will provide both the environment and impetus to the carrying out of much-needed scientific research, and at the same time will greatly aid research in these subjects themselves. They fear that the majority proposals to duplicate facilities in science will inevitably hinder the development of research both in science and in arts. They lay much stress on the development of post-secondary vocational education and the need for a wide extension and improvement of vocational and technical education in order that the schemes now being prepared by Colonial Governments under the Colonial Development and Welfare Act may be implemented. The majority report itself recommends the establishment of technical institutes for the dependencies of Nigeria, the Gold Coast and Sierra Leone, as well as the appointment of three technical officers to survey the existing facilities as a whole.

The minority report also recommends that each territorial college shall undertake the training of secondary school teachers, provide refresher courses for the non-graduate teachers of existing secondary schools, as well as a two-year course, following the school certificate course, for training primary school teachers; and the teacher training section of each college should experiment in the training of women teachers. Other proposals for a balanced educational policy include vocational courses for training social workers, a clear distinction between the training of social welfare workers, undergraduate study and postgraduate study and research. It is suggested that the territorial colleges should also act as extra-mural centres of the West African University College, and that it would be of advantage if the research headquarters of the Institute of West African Arts, Industries and Social Science were situated at Ibadan, though experimental stations and local research units would be maintained by it in all territories. In addition to the schools of medicine, agriculture, forestry and animal health, the proposed Institute of Education and a West African School of Engineering should also be established at Ibadan. The responsibility of recommending the creation of further institutions of university rank in West Africa would fall on the Inter-University Council proposed by the Asquith Commission; but in general the minority report suggests that it will be best to establish wholly new institutions rather than to attempt to convert territorial into university colleges.

As already indicated, the ably argued conclusions of the minority of the Elliot Commission appear to be more in keeping with the trend of the Asquith Commission than those of their colleagues; but individually and collectively the four reports present the university ideal in a way that gives them permanent value. That ideal is seen in relation to the present needs of the Colonial territories, and on the whole the immediate action required is clearly delineated with a large measure of agreement. Equally unmistakable is the note of urgency which runs through all the reports. The importance of university education is never over-stressed: it is always seen as part of a balanced educational policy as a whole. But it is clear also that unless university development in West Africa and the West Indies and elsewhere is not undertaken as a matter of great urgency, progress to self-government and real partnership will be retarded; and further, the economic and social development of these areas, and the implementation of developments under the Colonial Development and Welfare Act and the discharge of our pledges to build up social and economic institutions and to develop natural resources in these territories, will be retarded. The proposals of these reports merit full and sympathetic consideration: they involve close co-operation with the universities of Great Britain, co-operation on which the former Secretary of State for the Colonies rightly laid stress as a two-way traffic enriching the home universities as much as it is to the advantage of the Colonial territories themselves.

THE EARLY HUMAN EMBRYO

Ourselves Unborn

An Embryologist's Essay on Man. By George W. Corner. (The Terry Lectures.) Pp. xiv+188+8 plates. (New Haven, Conn.: Yale University Press; London: Oxford University Press, 1944.) 20*s*. net.

ALTHOUGH the embryonic development of man is one of the most copiously described of natural processes, until a few years ago there were several gaps in the story so far as it was known. The gaps, moreover, occurred at the most crucial stage, right at the beginning. Until a decade or so ago, the earliest known human embryos presented the picture of a minute vesicle, covered in villi and buried within the thickness of the uterine wall, the body of the vesicle consisting of a spongy tissue containing two small cavities between which the embryo reposed in the form of a flat plate. It was hard to draw any convincing analogies between this structure and that of the presumably comparable stages of other mammalian embryos. The early human embryo seemed aberrant in almost all its features; few other mammalian embryos bury themselves in the uterine wall, and no others were known with a similar development of spongy tissue, which might be considered either endodermal or mesodermal.

Our state of ignorance about the structure and affinities of early human embryos was dependent, of course, primarily on the difficulty of obtaining material for study. The opportunity to search a human uterus for recently fertilized ova is not an everyday occurrence even in a large hospital, and when it does occur, the difficulty of finding the minute object is considerable. Specimens from man's nearer anatomical relatives, the monkeys and apes, should theoretically be easy to obtain by special breeding; but that, again, is a most expensive proceeding, much beyond the resources of most embryological institutes.

In recent years the financial difficulties have been overcome with the aid of the generous funds placed at the disposal of scientific workers in the United States, and the Carnegie Institution of Washington has bred a supply of embryos of the Rhesus monkey. These have been fully studied and the crucial early stages described by Heuser and Streeter and others. At the same time, by an organized search on an adequate scale, a considerable number of very young human embryos have been discovered and investigated at the same Institution. Dr. Corner, who has recently become the director of the Department of Embryology in charge of these studies, made them the subject of his recent Terry Lectures, which have now been published in book form. He has thereby provided an account, both authoritative and easy enough for even the layman to understand, of the most recent advances in this field of human biology.

The new human material, and the even more complete series of forms from the Rhesus, show clearly that man's development is by no means so extraordinary as it appeared. Although no free blastocyst has been found, the earliest known stages show that man passes through such a form in a more or less normal manner. We have material which illustrates the immediately following stage, in which the blastocyst first adheres to the uterine wall and then burrows within it; and the monkey material shows that in other Primates too a similar process occurs. The new specimens allow us to examine in much more detail the formation of the extra-embryonic spongy filling of the trophoblast, and although the process is by no means fully understood, and correct attribution of the tissue to mesoderm or endoderm still remains largely a matter of choice, it is at least certain that, in this process again, man is closely similar to the monkey and the ape.

Dr. Corner describes the most important features of man's early Primate embryology with great clarity, and illustrates them not only with simple diagrams, but also with some of the beautiful photographs which have been a feature of the publications of the Carnegie Institution. He is, perhaps, less successful in attempting to attach profound philosophical importance to these facts. The Terry Lectures are, of course, concerned with "building the truths of science and philosophy into the structure of a broadened and purified religion", and a lecturer on such a foundation is specifically invited to step, for once, beyond the narrow confines of a rigid adherence to immediate appearances, and encouraged to exhibit the broader implications of his subject. History, however, has flowed on beyond the controversies in which the facts of descriptive embryology were sharp and dangerous weapons, and it is not easy now to make their import seem momentous. "In the foregoing pages," writes Dr. Corner, "I have outlined the evidence for two very weighty conclusions about the physical nature of man. The first of these is that he is an animal, a member of the Class of Mammalia, Order of Primates, and closely related to the apes and monkeys. The second is that the human body is not notably endowed with specialized anatomical features. . . ." One may admit that the conclusions are weighty; but it is difficult not to feel that the first at least is a commonplace. Dr. Corner's material is, in fact, of first-class scientific importance, as solid, incontrovertible data filling in a gap in the scientific picture; the attempt to 'write it up' as of immediate import to man's spiritual life leads to the interpolation of occasional passages which some readers may find jarring.

C. H. WADDINGTON.

CLASSIFICATION OF RECENT PHILOSOPHY

Process and Polarity

By Prof. Wilmon Henry Sheldon. Pp. xvi+153. (New York: Columbia University Press; London: Oxford University Press, 1944.) 13*s.* 6*d.* net.

THIS, the first of the Woodbridge Memorial Lectures, is a fine tribute to an American thinker recently dead, by one who shares a great deal of his philosophy and even more of his eminently civilized and humane attitude, his wide sympathies and his felicity of exposition. Prof. Sheldon classifies what he considers the important tendencies of recent philosophical thought, though without despising or distorting them, so as to bring out their relationship with his own views. His view of the nature of the opposition between rival philosophies is that each describes a genuine and important aspect of the world or general tendency of things, while apt to neglect others. Philosophers are generally right in what they assert, but wrong so far as they deny the reality or importance of the neglected aspects. Thus 'idealism' expresses the aspirations and insight of men as moral agents; 'materialism' the basic facts of existence, which the idealist despises (perhaps rightly) but ignores to his cost. Older attempts to effect a synthesis of these two extremes he calls 'scholasticism'—a recognition of the reality of both material and ideal as each playing a complementary part in an eternal divinely ordered scheme; for the scholastic order is fixed, reality eternal and temporal process entirely subordinate. Many recent thinkers (including the author) attempt a synthesis in terms of process, incremental change or evolution. Prof. Sheldon includes also in his scheme mysticism and scepticism, which are opposed in another dimension, as it were; and distinguishes two divergent forms of idealism, monistic and pluralistic.

Prof. Sheldon is a pragmatist so far as he takes thought to be essentially that which issues in action and is thereby put to the test; but he avoids the errors that come from despising reflective thought and from taking a commercial view of the ends of action. His statement (p. 22) that the full development of mental process requires all three phases, cognitive, æsthetic and practical, could scarcely be bettered. If this exposition could be taken as a preliminary sketch and the classification of philosophies as schematic and limited to the purpose of defining his own view, there would be nothing to find fault with. But apparently it is intended to be complete. Other types of opposition in thought, excluded from the classification, are dismissed as unimportant, ingeniously but not convincingly. The classification covers best those recent minor thinkers who fit readily into 'schools', but scarcely any of the great thinkers. The Greeks do not fit in; nor do Descartes, Spinoza or Kant. Excessive use is made of the ambiguity of the terms 'idealism' and 'materialism'. The notion of progress as change in any determinate direction is turned too easily into that of change which meets with our moral approval. Lastly, there seems no reason why those who recognize the importance of temporal process or progress in any sense should agree on anything else. There is as much difference between Herbert Spencer, Bergson and Prof. Sheldon as between any three philosophers taken at random.

A. D. Ritchie.

THE ANIMAL IN HEALTH

Physiology of Farm Animals

By Dr. F. H. A. Marshall and E. T. Halnan. Third edition. Pp. xi+340. (Cambridge: At the University Press, 1945.) 18*s*. net.

While most text-books on animal physiology are written from the point of view of the treatment of diseased conditions, this book by Marshall and Halnan is exceptional in that its object is the teaching of physiology as a basis for the management of the animal for production, normal health and growth. Animal physiology forms the fundamental science on which the teaching in the breeding, feeding and management of farm animals should be based. In the past, teaching in this sphere has been almost entirely based on practical animal husbandry rather than on the basal science. The science of animal physiology should in the future stand in the same relation to animal production as the science of botany has in the past stood as a basis for teaching in crop production in agricultural colleges. With the increasing demand for knowledge in the field of applied science and with the present emphasis on the livestock side of British agriculture, the new edition of this book, which has been out of print for some time, should supply a need for agricultural students and others interested in farm animals.

Naturally the functions of nutrition, reproduction including milk secretion, growth and locomotion find a larger place than in most text-books of physiology. In this respect it more nearly resembles the text-books of physiology of some sixty years ago. The present edition has been thoroughly revised and includes the results of recent investigations, particularly in the fields of nutrition and reproduction. The chapters on the energy requirements of the body, metabolism of organic and ash constituents, and feeding standards include much useful information on the results of modern research and are presented in a clear and simple form. A chapter on digestion and other facts concerning the fowl, so frequently neglected in modern books on physiology, is included. Similarly, the chapters on the male generative organs, the female generative organs including the mammary gland, and growth give the essential facts elucidated by recent research in a form which can easily be grasped by the student.

In detailing these results the research worker's name is given, but one misses, however, a short list of references to outstanding papers, books and reviews of the subject, which would enable the reader to continue with advanced study in any particular aspect in which he might be interested. The large number of illustrations makes the book particularly suitable as an introduction to the subject for the agricultural and veterinary student.

John Hammond.

A TEXT-BOOK OF HEAT

A Text-Book of Heat

By G. R. Noakes. Pp. viii+469. (London: Macmillan and Co., Ltd., 1945.) 10*s*. 6*d*.

To his successful volumes on optics and on electricity and magnetism, Mr. Noakes now adds a comprehensive text-book on heat "up to scholarship standard". Instead of taking the material of the older books, correcting obvious errors and including new matter merely with the object of securing encyclopædic completeness, he has wisely chosen the more philosophic plan of examining critically current ideas on the subject, in order to present them in such a way that the young physicist may receive a sure grounding in fundamentals rather than make an acquaintance with an excessive range of isolated facts and opinions.

Guided by his wide teaching experience, the author has deemed it necessary to challenge much that has become almost sacrosanct by dint of uncritical repetition in the past. Thus, definitions have been examined and often found wanting in precision; experimental results have been reviewed as to their meaning and application and, with characteristic and commendable boldness, old and inaccurate methods of measurement (the only claim of which to value was the doubtful one of respect for teaching traditions) have been omitted or relegated to a mere note in favour of up-to-date working practice hitherto scarcely touched upon in text-books of this standard.

The treatment throughout is highly original and stimulating. Physics teachers will take special delight in the presentation of thermometry, calorimetry, kinetic theory of gases, transference of heat and thermodynamics. The chapters on low temperatures and heat processes in the atmosphere provide a valuable survey of recent research in fields that have become of great importance to everyday life; indeed the realistic outlook of the whole volume, coupled with its sound statement of fundamental principles, would seem to render it a fitting guide to the 'heat' section of the course for the new National Certificates in Applied Physics, and to this end it may be strongly recommended to technical teachers.

Practising physicists who desire a refresher course in classical physics will find the volume both entertaining and instructive, especially if they attempt some of the searching numerical examples provided for exercise.

A NEW COSMOGONY OF THE SOLAR SYSTEM

FULL details of a new theory of the origin of the planets have now reached Great Britain from Sweden in a series of papers published by Dr. Hannes Alfvén in the past three years. The main theory is given in two of these papers[1], though references are made in these to preliminary work appearing in other Swedish periodicals.

Previous cosmogonies of the planetary system have started with some premise (more or less likely according to the state of knowledge at the time) as to the original spatial distribution, velocity and physical condition of the matter later to form the solar system, and of any neighbouring material required by the theory. The subsequent history of the matter is then decided by calculating the gravitational and other mechanical interactions involved, using the accelerations thus deduced to predict for the present time a new spatial distribution which should, of course, approximate to the present state of affairs. Dr. Alfvén breaks new ground by considering not merely the gravitational but also the electromagnetic interactions. Ions and electrons within the planetary system, he claims, are affected very much more by the sun's general magnetic field than by its gravitational field; and since at the time of genesis of the system the planetary matter is likely to have been at least partially ionized, it is probable that electromagnetic forces have been more important than mechanical forces in shaping the system as we see it to-day. From a study of the motion of ions in the solar magnetic field, he is led to attribute the formation of the planets to the passage of the sun through an interstellar cloud or series of clouds—a circumstance which, incidentally, is not so intrinsically unlikely as the close approach of another star required by theories of the 'catastrophic' type. Alfvén claims that in these conditions matter will accumulate in the equatorial plane at about that distance from the sun at which the present major planets are found. From this starting point he is able to explain many features of the solar system, even down to such details as why Saturn alone has rings, and why the rings show their observed structure.

It is relevant to recall here that the main difficulty encountered by cosmogonies of the Laplace type—the nebular hypothesis and its many modifications—concerns the peculiar distribution of angular momentum among the bodies of the solar system. A uniform discoidal nebula contracting from planetary distances would result in a system in which the main angular momentum was possessed by the central body, and no appeal to the effect of viscosity in redistributing it has yet convinced astronomers that this agency can convey 98 per cent of the momentum from the sun to the planets. On the other hand, a strongly condensed nebula of which the outer portions contain initially only enough mass to make the planets cannot in fact form planets at all. The tidal theory in its many forms also suffers from this difficulty. The encounter between the sun and a passing star postulated on this theory must be sufficiently close for tidal eruptions to eject enough planetary matter to form the solar system. But, as Russell has pointed out, it is then impossible (by a factor of the order of ten) for the planets to obtain their angular momentum at the intruder's expense. Furthermore, there is as yet no agreement as to the form taken by the filament of matter tidally extracted, or even whether it will dissipate or condense. The other time-honoured objection to tidal theories is the low probability of a close encounter. Now it is not a valid objection to an encounter theory that encounters are improbable: they may nevertheless happen, and all the objectors can justifiably claim is that planetary systems will be correspondingly rare. The discovery of non-solar planets[2] militates against this view. It is perhaps not an unfair summary of the present situation to say that those hypotheses which can claim an end-product most like the present solar system are precisely those which introduce the greatest number of *ad hoc* assumptions. Clearly, this is an unsatisfactory state of affairs.

In these circumstances, Dr. Alfvén roundly asserts that at the genesis of the solar system some kind of force must have been in action which is not taken into account in present theories. He believes that this force is the action of the general magnetic field of the sun on charged particles of primeval matter in motion in the solar neighbourhood, and his theory is an elaboration of this assumption.

In a preliminary paper[3], Alfvén has given reasons for believing that if a cloud of ionized gas invades the magnetic field of a rotating electrically conducting sphere, currents will be induced in the gas which will interact with the magnetic field so as to accelerate the ion cloud and retard the rotation of the sphere, thus tending to equalize the angular velocities. Applying this to the solar rotation, he comes to the conclusion that the time needed for this process (approximately 10^6 years) is very much smaller than the currently accepted age of the solar system, and thus that the transfer of angular momentum by this means is worthy of consideration. A further point of interest is that the rate of retardation is expected to increase with heliographic latitude, so that the non-uniform rotation of the sun observed at present may be due to this braking process in a past so distant that the planets have had time to form and acquire most of the original angular momentum, yet not so distant that solar viscosity has been able to equalize the solar rotation in all latitudes.

The theory starts, then, with the sun a single star in much the same condition as at present, save for a faster rotation. At the outset it enters a gaseous nebula consisting of neutral atoms with peculiar velocities corresponding to the temperature of interstellar space. These atoms begin to fall in under the sun's gravitational field, exchanging their potential energy for kinetic. At a distance r from the sun, the kinetic energy of an atom produced by gravitational attraction is

$$E = GM_{\odot}Am_H/r,$$

where G is the constant of gravitation, $M_{\odot}$ the sun's mass, A the chemical atomic weight, and m_H the mass of unit atomic weight. Mutual collisions between the atoms will result in a rising 'temperature' corresponding to this kinetic energy as r decreases; this process is similar to the heating by gravitational contraction suggested nearly a century ago by Helmholtz as the energy-producing mechanism in the sun. At a distance r_i from the sun, which depends on the atoms concerned, this energy becomes equal to the ionization energy eV (where V is the ionization potential). At this distance,

$$r_i = GM_{\odot}Am_H/eV,$$

the gas becomes ionized. Thence the system of forces is completely transformed. Electromagnetic forces come into play which are usually larger than the gravitational attraction, and the ions are repelled, spiralling away from the sun around the magnetic lines of force. Meanwhile, the process mentioned above begins to cause rotation about the sun's axis. A neutral gas falling into the sun from interstellar space is thus stopped at about the distance r_i from the sun. It is obviously interesting to calculate this distance for a hypothetical material. If $A = 7$ and $V = 12$ volts (values not unreasonable for planetary material) r_i is found to be 8×10^{13} cm., a value close to the radius of Jupiter's orbit. This is, of course, a drastic schematization of the actual conditions, for different atoms will be stopped at different critical distances; but it does serve to indicate that a gas cloud will tend to accumulate at about the distance from the sun of the major planets.

Atoms which become ionized on the spherical surface r_i can move only on the surfaces engendered by rotating the magnetic lines of force around the axis of the sun[4], for on account of their low kinetic energies they are constrained to perform close spirals around the lines of force, while rotating also about the solar dipole. Alfvén shows that, so far as its average trajectory is concerned, each particle may be replaced by an 'equivalent magnet' of moment

$$\mu = A m_H v^2 / 2H,$$

where v is the velocity of motion perpendicular to the line of force and H is the local field strength. This equivalent magnet is acted upon by a force $-\mu \operatorname{grad} H$ due to the non-uniform field, the minus sign indicating a repulsion down the magnetic gradient. For a given particle, stable equilibrium is possible only where its line of force cuts the equatorial plane; so that from the initial spherical shell of constant density the ions move to the equatorial plane, building up a disk of variable density by projection along the lines of force. Alfvén calculates the density distribution to be expected, and by assuming that all the material between the radius r_i and the orbital radius of Saturn has condensed into Jupiter, and all that between the orbits of Saturn and Uranus has condensed into Saturn, and so on, he obtains the following relative masses to be expected for the outer planets:

	Mass (Earth = 1)	
	Calculated	Observed
Jupiter	(317)	317
Saturn	87	95
Uranus	26	15
Neptune	10	17

The condensation process he invokes is one suggested by Lindblad[5], which depends on sublimation due to the great difference of temperature between the interstellar gas and solid particles. The process is favoured in the relatively dense accumulation in the equatorial disk, and may possibly occur after recombination of the ions in that neighbourhood. After recombination, only gravitation affects the particles, which then revolve in orbits of eccentricity 1/3 with their accrued angular momentum. Collisions then transform these orbits into a circle of radius equal to 2/3 of the distance at which recombination occurred, a fact which Alfvén later uses to explain much of the detailed structure of Saturn's rings and the asteroids.

The agreement in order of magnitude shown in the table above encourages an attempt to apply the same reasoning to the planetary satellites. If after formation of the outer planets some of the gas cloud remains uncondensed, and if the newly formed planets become magnetic dipoles, the process is likely to recur on a smaller scale. The residual gas will be attracted by the gravitational fields of the planets, will fall in towards the parent bodies and become heated, ionized and then stopped at certain critical distances by the magnetic fields. It is significant that in the case of Jupiter this critical distance is of the same order as the orbital radii of the Galilean satellites. With Saturn the critical distance is within the Roche limit, so that the material which would otherwise form the first satellite (the analogue of Jupiter in the solar system or of Io in the Jupiter system) cannot condense at all and forms the spectacular ring system. With Uranus and Neptune the mass is so small that the critical radius is of the order of that of the planet itself, so that neither satellites nor rings would be expected as a result of the primary process.

The theory thus accounts qualitatively and even, in some respects, quantitatively, for the observed mass distribution in the outer planets and their inner satellites—the first family, as Alfvén calls them. There remains the question of the second family: the terrestrial planets and the outer satellites of the outer planets. It is possible that the latter are the result of the primary process acting on those constituents of the interplanetary nebula which have high atomic weights or low ionization potentials (or both). It is sufficient to make $A = 30$ and $V = 9$ volts to get numerical agreement between the theory and observation. In this connexion it is satisfactory to note that the densities of the outer satellites of Saturn are considerably higher than those of bodies in the first family, whether planets or satellites. But to explain the formation of the inner planets on the theory as given above is impossible. Even for hydrogen, $A = 1$ and $V = 13{\cdot}5$ volts, giving $r_i = 10^{13}$ cm., so that penetration inside the orbit of Venus is impossible. At best, Mercury would be non-existent and Venus a mass of pure hydrogen!

As a working hypothesis offering a way out of this difficulty and accounting simultaneously for both the planets and the satellites of the second family, Alfvén suggests that the primeval material from which the inner planets were formed consisted of solid particles resembling meteoric dust. These can penetrate much closer to the sun than atoms: for unlike gas ions, dust particles will be practically unaffected by the general magnetic field, which will take effect only when the particles are near enough to be partly volatilized. If volatilization and ionization occur in the region of the inner planets, the ions will be repelled at once along the inner lines of force and will accumulate in the equatorial plane and start rotating exactly as in the formation of the first family. Hence the terrestrial planets. A small proportion approaching the sun's poles will be repelled as far as the outer planets and on recombination will form satellites distinguished from those previously considered by the high value of A/V characteristic of meteoric matter, and thus by larger values of r_i than first-family members. Alfvén identifies this family with the outer moons of Jupiter and Saturn and the satellites of Uranus and Neptune. For $A/V \sim 5$ volt^{-1} the critical distances r_i are of the right order; and this value is not unlikely if meteorites reaching the earth are typical in their chemical composition (oxygen, 1·2; iron, 7·2; silicon, 3·5; magnesium, 3·2).

Further development of the theory enables Alfvén to explain in some detail certain features exhibited in the densities and axial rotations of the planets and their satellites; but enough will have been said here to give the broad principles of the theory he has advanced. Two circumstances militate against its widespread acceptance at present. First (and this applies to any cosmogony) the nature of the problem is such that any theory must be developed from premises which are largely guesswork, and can have few points at which direct observational checks can be applied. Second, during the past six years international exchange of scientific periodicals has been in so chaotic a condition, and so few astronomers have been free to conduct abstract studies, that much potential criticism has yet to be formulated. The end of the War in Europe will, no doubt, quickly remedy matters in respect of this second point, but the first will remain. Alfvén's hypothesis cannot hope to escape the criticism which has been so freely bestowed upon its predecessors. For example, its very basis, that the sun possesses a general magnetic field, has in another connexion been challenged from the observational point of view[6]. Furthermore, calculation of the trajectories of charged particles in non-uniform fields is not an elementary matter, and Alfvén's treatment of the problem may be attacked. But he will have performed a valuable service to astronomy if this series of papers can establish that electromagnetic forces have in the early stages of the solar system played a part even comparable with those mechanical forces which have hitherto been the only ones considered. THE SCAPEGOAT IN MODERN EUROPE

IN view of the important and unhappy part played by scapegoats in the political field in recent years, the general theme of the scapegoat in modern Europe was a well-chosen one for a joint meeting of the Royal Anthropological Institute and the Social Psychology Section of the British Psychological Society held in the rooms of the Institute on July 3, Prof. Daryll Forde being in the chair. It was perhaps unfortunate that most of the speakers allowed themselves great latitude in the interpretation of the subject, with the result that less light was thrown upon contemporary aspects of scapegoatism than might have been hoped for. Nevertheless, the great significance of the theme in human history and culture was well illustrated by the discussion, as was also the amazingly wide range of social phenomena in which it may play a part.

Dr. J. C. Flugel, in opening the discussion, outlined his view regarding the general nature of the psychological processes involved. The use of scapegoats involves the general process of 'displacement', 'substitution' or 'deflexion', that is, the transference of an impulse from one object to another in virtue of association or conditioning, the particular kind of displacement here involved being the projection of aggression, guilt or suffering. It is theoretically possible to distinguish between the transference of simple misfortune (for example, barrenness or disease) and of guilt; but in practice the distinction is often difficult, since misfortune is often regarded as itself in the nature of a punishment for guilt, and the use of a scapegoat is then only a means of shifting the burden of punishment. In the view of many psychologists, the spirits or demons that in primitive beliefs are responsible for so many human disasters are themselves mental creations due to the projection of human aggressiveness, which in this form recoils on those in whom the aggressiveness originated.

A full psychological understanding of scapegoatism thus necessitates a consideration both of projection and of the role of punishment. Projection (the attribution to others of qualities in ourselves) arises from, and in some sense perpetuates, the confusion between the self and not-self to which child psychologists have directed attention, a confusion to which in some measure we return as we fall asleep or dream and which can even be experimentally induced by the adoption of certain attitudes (as in Spearman's interesting 'experiments in objectivating'). Projection is also due in part to the general tendency to establish the equation: 'good'=self, 'bad'=not-self. The child soon discovers that what is 'bad', that is, painful, disturbing and (later) 'naughty', can often be dealt with either by destroying the 'bad' outer object or removing himself from it, whereas when the 'bad' is within the self, either in the form of unpleasant bodily sensations or mental uneasiness or guilt, there is no such possibility; hence there arises a natural desire (in virtue of a primitive form of 'wishful thinking') to place everything that is 'bad' in the category of the not-self. Projection is complementary to introjection (the attribution to the self of qualities of persons or things in the outer world) and the child-analysts consider that the two processes —one following the other in long alternating sequence —play an important part in mental development. Projection is also allied to such processes as these in virtue of which a man identifies himself with his children, family, possessions or country (W. James's 'extracorporeal' or 'social-selves') or finds a vicarious satisfaction in the triumphs or enjoyments of others (Anna Freud's 'altruistic surrender'). The projection of aggression in a form relevant to the theme of scapegoatism is clearly seen in many childish phobias, where the bogies feared (for example, fierce animals or ogres) owe their terrifying qualities to the child's own aggressive impulses. There is good reason to suppose that the psychological process here is fundamentally similar to that involved in the alarming features of the primitive animistic beliefs in demons and evil spirits already referred to. Projection of the same kind is also at work in delusions of persecution or jealousy, where the patient's own 'evil' wishes are attributed to the supposed persecutors.

Turning to punishment, Dr. Flugel said that this is a fundamental method of dealing with guilt. There is in the human mind a deep tendency to expect, and indeed to demand, that guilt should be atoned for by punishment, though in virtue of projection the punishment can sometimes be suffered vicariously by a scapegoat. Some persons are more inclined to blame, and inflict punishment on themselves, others to project the blame and inflict vicarious punishment. On the basis of recent experimental studies, these have been called by Rosenzweig the 'intro-punitive' and 'extra-punitive' types respectively. Minor forms of scapegoatism can be seen in children's play and fantasy, where dolls or 'imaginary companions' can get into scrapes and receive appropriate punishment of a kind which may previously have befallen the children themselves; the 'bad' impulses are here projected on to the toys or fantasy-figures. In adult life the same tendencies may manifest themselves in scandal-mongering, in purity campaigns, in our attitude to criminals and in educational practice. In all these cases the persons blamed or punished are guilty of actions to which we ourselves are to some extent tempted, and in administering censure or punishment on the scapegoats, we are also putting things right with our own conscience. A great advantage of the use of scapegoats is that we can feel virtuous ourselves. In the field of religion there is the important category of divine scapegoats who are sacrificed to atone for guilt. It is at first sight strange and paradoxical that so many sacrifices *to* a god are also sacrifices *of* that god (in direct or symbolic form). A further but connected problem is raised by the fact that in these cases the scapegoat is 'good'. The solution of both problems is probably to be found in the existence of 'ambivalence' on the lines indicated by Freud in his theory of totemism.

Finally, there is the class of political scapegoats who have played so great a part in recent years. Hitler, in accusing the Jews of seeking world dominion, was, of course, projecting on to them his own desires, and in so doing succeeded in making the Nazi designs appear supremely righteous to himself and his followers. Quite generally, the use of political scapegoats is a potent means of disposing of the aggressive impulses in the members of a group without disrupting the group. Indeed, by attributing every kind of evil design to the scapegoat and thus apparently necessitating a united front against him, this psychological device can greatly increase the internal cohesion of the group. Hence the great and sinister role taken by the scapegoat motif in inter-group conflict throughout human history.

Dr. M. A. Murray, who was the second speaker, confined herself to two main themes: the relation of the scapegoat motif with fertility, and its manifestation in the death of political scapegoats during a certain period of English history (from Edward I to the end of the Stuarts). Scapegoats, she suggested, were found only in agricultural, not among pastoral, peoples. There are at bottom three origins of the idea of the scapegoat: (1) Sin causes barrenness of the soil; in order to avoid this calamity the sins of the community are laid on one person, who is killed or driven out. (2) The spirit of fertility becomes incarnate in a man (the 'god-box'). If this man grows weak or dies, fertility will diminish or disappear; therefore the 'god-box' must be killed with due ceremony while still strong, and the spirit put into a young and lusty 'god-box'. (3) Life is taken out of the ground by the crops, therefore life must be given back to the ground. This can be done by pouring the blood of the victim on the ground, by burning him and strewing his ashes on the ground, and by asphyxiation, when the body is dismembered, the pieces of his flesh being distributed over the land (connected with the custom of drawing—in the sense of disembowelling—and quartering the body of a traitor or criminal).

The spirit of fertility is most naturally incarnated in the person of the king or ruler—for whom, however, a substitute or scapegoat can be found. (A relic of this is to be found in the English coronation ceremony at the moment when the king, after the anointing, stands alone divested of his outer robes and clad in white, while those officiating step away from him.) In the course of time this whole process is apt to become stylized and connected with certain cycles (mostly seven- or nine-year cycles), the origin of which is still far from clear, though there is no doubt it is of great antiquity. The sacrificial months of the Old Religion (which Dr. Murray calls the 'Dianic cult') were February, May, August and November. The right days for the sacrifice were February 2, May 1, August 1 and November 1, though these were not always observed when the custom began to die out. The periodic sacrifice most marked in English history is that of the seven-year cycle. The victim was slain when the king's age had reached a multiple of seven years (personal victim), or when his reign had reached seven or a multiple of seven years (regnal victim). Among notable victims might be quoted:

William Wallace, Mock King. Executed August 23. Edward I's age, twenty-one.

Piers Gaveston, Mock King. Surrendered to the barons on condition that no harm should happen to him until August 1. Beheaded. Edward II's age, twenty-eight.

Duke of Clarence. Murdered (in a butt of malmsey ?) February 18. Edward IV's age, thirty-five.

Perkin Warbeck, Pretender to the throne. Executed November 23. Henry VII's age, forty-two; reign, fourteen.

Cardinal Wolsey. Died November 29. Henry VIII's reign, twenty-one.

Dr. Murray suggested that the fact that there was always a victim in England upon whom the people could vent their sense of guilt at periodic intervals may be a cause of the tolerance which is so marked a feature of the English as compared with most other nations.

Further to the subject of national differences, Dr. Margaret Loewenfeld, in opening the general discussion, remarked on the differences in the attitude of various cultures to the expression of feeling. Although in Britain emotion is often considered disreputable, members of other cultures (for example, in their different ways France and Germany) might feel they have a right to certain emotional experiences (such as that implied in 'thinking with the blood'). In such circumstances those who do not feel in the same way become an out-group, and in time of frustration it is inevitable that the out-group should become a scapegoat. She illustrated this by reference to the Suffragette movement and the attitude of members of the Stock Exchange to 'bucket shops'.

Dr. Ernest Jones emphasized the importance of distinguishing between scapegoatism and simple aggression. The Nazi use of the Jews as scapegoats probably depended largely on the fact that Germans were at bottom disturbed by the imputation of war guilt; but instead of resorting to sackcloth and ashes (as the ancient Hebrews might have done) they projected their guilt. We may, he said, never have another such opportunity of studying scapegoatism on the grand scale, and he was disappointed that the discussion had not dealt more in detail with recent events. He suggested further that the Germans did not look for scapegoats so much among their foreign enemies as among themselves, and found them among their own Jews and Communists. This may be connected with the fact that, as psycho-analysis has shown, the child builds up an idea of good or bad 'internal objects'. In answer to a question, he admitted the feeling against international Jewry, but he thought this might be only because there are German (or English, etc.) Jews.

The distinction between guilt and simple aggression was further brought out in the remainder of the discussion, which dealt, among other things, with the guilt feelings of Britons and Americans at not being adequately prepared for Nazi or Japanese aggression, with the fact that the chosen scapegoat need not necessarily be innocent as judged by rational standards, and with the possible existence of rudimentary guilt and scapegoatism in animals.

THE ATOMIC BOMB

A PAMPHLET, "Statements relating to the Atomic Bomb", published by H.M. Stationery Office (price 4*d.* net), gives some account of the activity in Great Britain and the United States leading to the use of this weapon in Japan by the United States Army Air Force. Reference is made to statements issued by the United States and Canadian Governments giving an account of the work carried out in these countries which led up to or was associated with the achievement, and an outline of the scientific background. The statement includes a brief summary of earlier work on nuclear disintegration which bears only indirectly on the phenomenon of nuclear fission, on which the activity of the atomic bomb depends, and then gives some account of the work on the fission of uranium nuclei, published prior to the beginning of the War, and the development of which on a large scale led to the atomic bomb.

In 1934 Fermi and his colleagues in Rome subjected uranium to neutron bombardment and showed that new isotopes were formed which were radioactive, and it was thought that atoms of atomic number higher than 92, that of uranium, had been produced. These elements were not known in Nature. In 1938–39, however, Hahn and Strassmann, in Berlin, made experiments which showed that one, at least, of the new isotopes believed to be of higher atomic number and mass than those of uranium was really an isotope of barium, which had an atomic number and mass about half that of uranium. Frisch and Meitner thereupon pointed out that a phenomenon which they called 'nuclear fission' had occurred, the uranium nucleus being split into two parts of roughly equal mass, and that the two parts of the divided uranium nucleus should fly apart with great energy, a prediction verified experimentally by Frisch in Copenhagen. Confirmation of this fission process, and of the great liberation of energy, was independently obtained by Joliot in Paris, and by many other physicists.

Early in 1939, Joliot, Halban and Kowarski proved experimentally what had been predicted theoretically, that in the fission of uranium, a number of free neutrons were also produced, and independent confirmation was obtained by Anderson, Fermi, Hanstein, Szilard and Zinn in the United States. It was clear that the fission not only provided a large amount of energy by reason of the loss of total mass which had occurred, according to Einstein's theory of the correlation of mass and energy, but also that the liberation of neutrons in the process, which was produced by neutron bombardment, suggested that each time a uranium nucleus underwent fission, the reaction might be accelerated by the neutrons which it itself produced. It would, in fact, be analogous in the field of nuclear chemistry to the well-known chain reactions in the chemistry of stable atoms and molecules. The process could be started by the application of only a minute fraction of the energy which would ultimately be liberated.

Bohr and Wheeler had published a theory of the fission process in 1939 in which it appeared that the isotope of mass 235, present in only small amount in natural uranium, which consists mostly of the isotope of mass 238, should undergo fission particularly easily when the bombarding neutrons had a very low energy, whereas the isotope of mass 238 requires high-energy neutrons. This prediction was verified in 1940 by Nier, and by Booth, Dunning and Grosse, in the United States. Neutrons of an intermediate energy-range are strongly absorbed by the uranium 238 nucleus; but instead of producing fission, a new nucleus of mass 239 is formed. This has the property of emitting two electrons in succession, thus forming nuclei of atomic numbers 93 and 94, which do not occur in Nature. The nucleus of atomic number 94 should be capable of undergoing fission with the greatest ease when bombarded with neutrons of very low energy. The elements of mass 235, 238 and 239 are not the only ones which should undergo fission; thorium should undergo fission with bombarding neutrons of very high energy, and protactinium (mass 231, atomic number 91) should behave in a way intermediate between uranium 235 and 238.

The energy liberated in uranium fission is stated to be millions of times greater than that set free in the combustion of an equal weight of oil or coal; but the process must obviously be controlled, and a suitable 'slowing-down' medium is necessary, so that fast neutrons produced by fission would lose their energy by elastic collisions before producing further fission. Such a medium is provided by heavy water, or deuterium oxide. In an atomic bomb a quantity of uranium 235 greater than a certain critical amount is necessary. This is because the reaction depends on the conservation of the neutrons produced by the fissions. In a block of uranium, the proportion of neutrons which escape into the outer air, and thus become ineffective, is reduced by increasing the size of the block, and explosion is possible only with a certain minimum amount of material. Quantities less than this are perfectly safe. Thus, it is only necessary to bring together two pieces each less than the critical size, but exceeding it when in contact, to detonate the bomb. It is stated that the temperature of the mass then reaches many million degrees and the pressure many millions of atmospheres. The reaction must develop so rapidly that a substantial part of the material can react before the system has time to fly apart, and the neutrons produced in the fission process are fast enough to fulfil this condition, unless they are slowed down by artificial means.

Details are given of work at Liverpool and Cambridge on the dimensions of the bomb and related problems, and on the method of separation of the uranium 235 isotope by a gaseous diffusion method at Oxford and Birmingham. During this period, similar problems were occupying American scientific men. In 1942, it is stated, it became clear that the scale upon which research and development could be undertaken in the United Kingdom must be far smaller than in America. In 1943 a large research establishment was set up in Montreal, Canada, and in 1944 a British-Canadian-American project was in operation near Petawawa, Ontario.

The report gives the constitution of many committees set up, and of Government actions at various stages, and is a record of well-co-ordinated and actively prosecuted effort in the many directions necessary before the atomic bomb became a reality.

ARCHIVES OF THE LAKES

WE are just now being made aware that there exists a remarkable series of records of the history of Europe throughout the whole period since the great ice sheets began to release their hold on the Continent. These records are entombed in the deposits of our lake basins. We have hitherto been unable to read these archives; but the methods of pollen-analysis have given us the clue to their broad interpretation, and the story of forest history, of climatic change, and of human activity is discerned with increasing clarity. We have learned from de Geer that these records can, in some circumstances, be accurately dated; the lake deposits sometimes indeed consist of leaves, one page laid down per year, so that a precise geochronology of the past ten thousand years or so has been placed in the hands of the archivist.

A glimpse of the remarkable wealth of information such records may disclose is afforded by the recently published work of Max Welten on the deposits of a single tiny filled-up lake basin in the Simmental in the western Bernese Oberland[1]. This *Faulenseemoos* lies at a height of 590 m. above sea-level, on the road between Spiez and Interlaken, and here M. Welten, a pupil of Dr. Lüdi in Zurich, has carried out co-ordinated research on pollen-analysis, stratigraphy, and geochronology. Twelve detailed pollen-diagrams, distributed along a profile of the lakelet's length, which is only about 500 m., give a complex but consistent picture of the vegetational history of the region round the lake, which has been steadily filling in throughout post-glacial and late-glacial times. The lake was oligotrophic only for a short while, and then rapid infilling took place from land surfaces laid bare by the glacial retreat. With complete vegetational cover of the countryside, however, the infilling became slower. Heavy deposits of lake chalk were made round the shallow margins while the deep centre deposits grew very slowly, and then, as the climate grew warmer, organic material formed too rapidly for total oxidation aud nekron-mud (*gyttja*) was laid down. Thence followed a yearly periodicity of chalk deposition caused by influx of mineral-rich water in early summer, and of nekron-mud in autumn and early winter. Thanks to the small size and shelter of the lake, these annual layers were preserved in long series, and have permitted the construction of a geochronology which reaches to the present day. In terms of this all other stratigraphic, climatic and vegetational events have been dated. More also than this: the recognition of annual layering has permitted Welten to express his results in terms of absolute rates of pollen deposition per unit area of lake surface. He has thus provided the test we have long awaited, of the validity of the standards of reckoning, long accepted *faute de mieux*, such as grains per cent of the total tree pollen, or grains per unit area of microscopic preparation.

There has always hitherto been much room for doubt how far the parallel and analogous changes in forest history in the Alps and in regions far afield were indeed synchronous, but Welten's new chronology goes far to set such doubts at rest. His date of 5400 B.C. for the sudden extension of the mixed oak forest in *Faulenseemoos* corresponds closely with that given by Fromm for the equivalent vegetational change in Ångermannland. Confirmation of Welten's own chronological series comes from such results as the estimated age of the end of the Neolithic period at 1800 B.C., a close agreement with archæological estimates.

From the relative and absolute amounts of the lake chalk, organic mud and mineral matter, Welten is able to deduce climatic conditions, as also from the vegetational changes recorded by the pollen analyses. The regional vegetational history begins with the early dwarf-willow stages when the soil was open to erosion; the middle dwarf-willow – grass stages with closed ground cover and abundant *Helianthemum alpestre*; the third willow stage with extension of the dwarf-birch and entry of the tree birches. Continued climatic improvement then led to an explosive but temporary expansion of the sea-buckthorn (*Hippophaë rhamnoides*) in conditions of slight competition, and then to successive phases of dominance by *Betula pubescens* and *B. verrucosa*. About 6150 B.C. a climatic retrogression broke the trend of general amelioration, but thereafter the open pine woods were rapidly succeeded by hazel scrub, and afterwards by mixed oak forest. About 3200 B.C. beech became dominant, and thereafter persisted, in varying relation to the spruce and mixed oak forest, as an important forest component to the present day. Early human activity is reflected in the diagrams not only by changes in the pollen frequency, but by the appearance of cereal pollen, by increase in mineral deposition in the lake, and by the pollen of such introduced trees as the walnut. These elaborate and exactly dated diagrams will be of the utmost value to the study of quaternary history in central and southern Europe, and the work as a whole deserves our own attention and emulation.

Such studies as this show the manifold indexes by which the deposits of former lakes may be made to yield the secrets of their history, and of the vegetational changes which they and the surrounding areas have suffered through the long period since the Ice Age. Apart from its own great intrinsic interest, such knowledge affects biological and climatic issues of great and general importance, and constitutes a background essential to our attempts to understand the meaning of present vegetational types and present vegetational processes of lake biology. It is very much in the interest of British biology that means should be found to pursue such studies as these in our own lake basins, where at least equally rich rewards may be expected. Let us appoint and train these archivists.

H. GODWIN.

OBITUARIES

Dr. Alexander Sand, F.R.S.

IN the completely unforeseen death of Alexander Sand at the age of forty-three, comparative physiology suffered a very severe loss. Not only was his later work distinguished in a remarkable degree, but so much more of the same calibre might have been expected from him in the next twenty years.

Sand's early work dealt with changes in electrical resistance accompanying the death of cells, and with the relation of combined nitrogen to the physiological activity of *Azotobacter*. After his appointment as lecturer in zoology at Capetown under Hogben, he undertook a series of experimental studies dealing with invertebrates, the first of which described the relation of electrolytes to the cardiac rhythm of *Jasus* and *Octopus*, the others the respiratory exchange of certain arthropods (a crab and a scorpion) and of a marine worm (*Bispira*). This work was accompanied by determinations which were made by Sand of the hydrogen-ion concentration and oxygen-content of samples of sea water, in connexion with studies undertaken by colleagues. His next work concerned chamæleons. After a peculiarly neat and illuminating paper describing adequately, for the first time, the mechanism of the projection of the chamæleon's tongue (1933), he published another important paper describing the bionomics and physiology of the pigmentary activity of this animal. These papers were followed by a contribution to *Biological Reviews* on the comparative physiology of colour-response in reptiles and fishes.

After Sand's return from Cape Town to England he was appointed physiologist to the Marine Biological Laboratory at Plymouth, and thenceforward his interests were devoted to experiments on fishes, dealing primarily with certain of their sense organs. He published in 1936, in collaboration with James Gray, papers on the locomotory rhythm and spinal reflexes of the dogfish. After a preparatory period, during which he mastered the complex and delicate apparatus required, Sand attained the height of his ability and began his final work on the sense organs. This work, carried out partly in collaboration with Otto Löwenstein, involved a series of precise and beautiful experiments, and resulted in a most marked and definite advance in our knowledge not only of the labyrinth of fishes, but also of the lateral sense organs and of the peculiar ampullæ of Lorenzini. It is this last body of work for which Sand will be longest remembered, and which entitles him to rank high among British comparative physiologists. He was elected to the Royal Society in 1944. Two of his collaborators, Gray and Löwenstein, have already been mentioned; but during his whole career Sand also published joint papers with Lancelot Hogben, Enid Charles and others.

One of Sand's outstanding characteristics, the precision of his use of experimental apparatus, came out not only in his research work but also in his teaching. During his years at Cape Town he conducted a class in comparative physiology which was distinguished by its finished and flawless demonstrations. Sand served in the Royal Navy during the Second World War, and died on July 11, 1945. His death has come as a great shock to his many friends.

T. A. STEPHENSON.

Prof. Ludwik Wertenstein

THE tragic death of Prof. Ludwik Wertenstein, who was killed in January during the battle for Budapest, deprives Poland of one of its leading men of science, and represents a grievous loss to physicists generally, among whom he had many personal friends.

Born in Warsaw in 1885, Wertenstein received his early education there and entered the University, which he had, however, to leave in 1906, after one year of study, because of taking part in the students' protest strike against the policy of the Tzarist regime. He went to Paris, where he entered the Sorbonne and began to work in Madame Curie's laboratory. His first scientific work was published in 1909 and was soon followed by a series of papers dealing mainly with the properties of recoil atoms of radioactive elements, a subject which, with his usual thoroughness, he pursued and studied for many years. He measured the range, ionization and charge of recoil atoms, and some conclusions of these experiments were recently confirmed in the study of the ionizing properties of fission fragments.

In 1913, the Scientific Society of Warsaw founded, under the auspices of Madame Curie, the Radiological Laboratory, where research work on radioactivity was to be centred. Madame Curie sent her two most outstanding pupils, Danysz and Wertenstein, to Warsaw to direct the work there. After the death of Danysz in 1914, Wertenstein became director of the Laboratory, and he remained there until its destruction in 1939. In 1919 he was appointed to the chair of radioactivity at the Free University of Poland, where he later founded the Laboratory of Atomic Physics. Except for the period 1925–26, which he spent at the Cavendish Laboratory under the late Lord Rutherford, all his scientific work was done in these two laboratories. Despite the constant difficulties and limitations due to lack of funds, he managed to create a centre of research which gained a high reputation abroad, and to form a school from which came a number of young men of science of standing.

Most of Wertenstein's scientific work was in the field of radioactivity; he made a detailed study of the properties of radon, found new methods for its purification, investigated its condensation properties, measured its vapour pressure and ionization potential, and determined the volume of one curie, an important quantity in radioactivity. But his interests embraced many other branches of physics, and among the large number of papers he published are some on such divergent subjects as vacuum technique, photochemical law and isotope separation. In recent years, he concentrated mainly on nuclear physics, in particular on problems of inelastic scattering of neutrons, photonuclear effects and fission. His last paper, on gaseous fission products, published in *Nature* of December 29, 1939, was sent out of Poland when it was already occupied by the Germans.

Apart from pure scientific work, Wertenstein took an active part in the organization and popularization of science in Poland. He was a member of the Academy of Technical Sciences, and president of the Physical Society of Warsaw. His agile, penetrating and critical mind, swift reasoning, and almost uncanny facility for operating with figures mentally, made every discussion in the Physical Society a lively and exciting event. His was a most remarkable and versatile mind; apart from being a brilliant experimenter and highly skilled in various techniques, he was an excellent theoretician and had a deep knowledge of mathematics. He spoke fluently many languages, was a classical scholar and had great literary talent. His quickness and wit, combined with a deep sense of humour, made him most popular at all scientific and social gatherings. An excellent speaker, he had a particular gift of presenting difficult problems in a simple manner, and his public lectures—masterpieces in language and composition—always attracted large audiences. His articles in various magazines and Sunday papers contributed a great deal to the popularization of science in Poland. He translated a number of books into Polish, the last being Madame Curie's "Radioactivité"; the translation of this was just finished when war broke out, and it achieved the unique honour of being published by the underground movement; it was the main scientific book used by the students of Poland's Underground University, in which Prof. Wertenstein took an active part. Little is yet known about his fate during the war years; but he was hunted by the Germans and had to hide in various parts of the country. Finally he managed to escape to Hungary, and there, on the eve of the liberation of Budapest by the Red Army, he was killed by a shell fragment during the battle for that city.

I cannot end this note without a tribute to Prof. Wertenstein's character and personality. He possessed such virtues as made him an outstanding man even without his scientific achievements. He was exceptionally kind, generous, friendly and utterly unselfish. Everyone who knew him was charmed and attracted by his cordiality, cheerfulness and modesty. But we, his students, who worked with him closely, could most fully appreciate the integrity of his character. He was not merely a teacher but also a friend and counsellor; he cared not only for our intellectual needs but also for our general welfare, and would not spare any efforts to meet any of our difficulties. He will always remain in our memory a symbol of the ideal man of science, a perfect blend of brilliance and kindness, erudition and good humour, enthusiasm for Nature and love of humanity. J. Rotblat.

Prof. Walter Makower, O.B.E.

The death of Prof. W. Makower at the age of sixty-five occurred on July 7. Makower graduated from University College, London, where he took honours in chemistry; but going to Cambridge as a research student under Thomson effected his transformation into a physicist, and his M.A. was for a thesis on the diffusion properties of radium emanation (radon). From the Cavendish Laboratory he went to Manchester as a John Harling Research Fellow under the directorship of Schuster. On the latter's retirement in 1906, Makower became lecturer on the staff of Rutherford, whose arrival in Manchester gave a great impetus to radioactive studies. Over a period of years Makower did experimental work in this subject; he showed that radium *A*, *B* and *C* all had different temperatures of volatilization and that the behaviour of the active deposit depended largely on the pressure conditions within the vessel. Later on he collaborated with Prof. S. Russ on radioactive recoil, with Fajans on the beta-rays from radium *B* and with Moseley on the gamma radiation from the same substance; with Geiger he wrote a timely book on radioactive measurements. He had previously written one of the earliest books on radioactivity entitled "The Radioactive Substances".

Outside the precincts of the Physics Department, Makower spent a good deal of his leisure at the kite-flying station installed high up on the moors above Glossop in Derbyshire. He escaped injury when the kite he was flying was struck, setting on fire the hut in which the winding machinery was installed.

The War of 1914–18 found him serving first as a lieutenant R.N.V.R. and then as a captain R.F.C.; both positions he filled in a scientific capacity.

After sixteen years service in the Physics Department at Manchester, Makower became attached to the research laboratory of the Dunlop Rubber Company, but he was glad to return to professional life when appointed in 1925 to the post of professor of science at the Royal Military Academy, Woolwich. This post he held until 1938 when he resigned; he was awarded the O.B.E. in 1934.

During the years of retirement he did valuable work for the Institute of Physics.

Walter Makower came of a cultured family, all the members being musical; he was no mean performer on the 'cello. Those who knew him intimately valued him most for his sense of humour and his integrity of mind. He married Dorothy Lois Drey who, with their two daughters and a son, survives him.

Miss E. R. Saunders

The obituaries of Miss E. R. Saunders in *Nature* of August 18, 1945, while describing her morphological and educational work, do not refer to her contributions to genetics. These were, however, of the first importance. In 1897 she began experimental plant breeding at Cambridge in collaboration with Bateson, and the results were presented to the Evolution Committee of the Royal Society in 1901. Meanwhile Mendel's work had been rediscovered in 1900. By 1901 she had established the existence of Mendelian inheritance in *Lychnis*, *Datura* and *Matthiola*. It is clear that she and Bateson had independently rediscovered some at least of Mendel's laws before his work was known to them. She must in fact be regarded as the 'mother' of British plant genetics.

Her later genetical research was mainly on *Matthiola incana*. Here she successfully analysed what was then the most complicated known case of genic interaction. Any of four independent recessive genes may render a plant of this normally hoary species glabrous. Two of them also make it white. She also described, in connexion with doubleness, what, in modern terminology, is the first case of balanced lethals, and the second case of linkage. Up to her death she continued to display a lively interest in all branches of genetics, and was treasurer of the Genetical Society. To all geneticists her death was a loss; to many a personal loss. J. B. S. Haldane.

Dr. G. V. Buchanan

Dr. Gwynneth Vaughan Buchanan, senior lecturer in zoology at the University of Melbourne, died towards the end of June 1945. Dr. Buchanan was born in Sydney in November 1886, and was educated at Toorak College and the University of Melbourne. For a time she acted as professor of zoology in the University of Western Australia before she returned to her old university as senior lecturer under Sir Baldwin Spencer. To English zoologists she is perhaps best known for her outstanding work on the development of the marsupials, undertaken in conjunction with Dr. Elizabeth Frazer at University College, London, in 1918. In Australia, the great influence for good that she exercised on the many students to whom she was so much more than a mere university teacher will long be remembered. It was largely owing to her influence and enthusiasm that the McCoy Society for Field Investigation and Research came into being and became such an outstanding success. After some months of ill-health, bravely borne, she retired from active teaching in February of this year, but until the last she continued her enormous correspondence with old students scattered, by the War, to distant parts of the world.

F. Wood Jones.

NEWS and VIEWS

Chemistry at Leeds: Retirement of Prof. W. R. Whytlaw-Gray, O.B.E., F.R.S.

PROF. ROBERT W. WHYTLAW-GRAY is retiring from the chair of chemistry in the University of Leeds at the end of this month after twenty-two years service. During his administration, the Department of Chemistry has undergone many changes, including its entry into a new building, in the design and equipment of which he took a leading part, and which has proved to be almost ideally arranged for both teaching and research. Throughout his academic life at University College, London, in Bonn, at Eton or in Leeds, Prof. Whytlaw-Gray has devoted himself wholeheartedly to research work, whether in pursuit of exact knowledge for its own sake or (for the second time) in the application of his special experience to his country's war-time problems. Before going to Leeds, he had developed a technique for the examination of smokes with the ultra-microscope which led to the determination of particle size and number, and to the discovery that these aerial systems, unlike the more familiar hydrosols, are unstable and undergoing continuous coagulation. At Leeds, with the help of collaborators, notably Dr. Colvin, Mr. H. S. Patterson and Dr. W. Cawood, the coagulation process was fully explored, new methods developed both for counting the particles when suspended and after sedimentation, and, in a series of papers, the kinetics of smoke coagulation established on a sound quantitative basis. The results of these investigations and their bearing on aerial systems in general were summarized in the Liversidge Lecture delivered before the Chemical Society in 1935 and in a book entitled "Smokes" written in collaboration with H. S. Patterson.

Prof. Whytlaw-Gray has always been much interested in the determination of the atomic and molecular weights of gases by physico-chemical methods, and many investigations in this field have been made in the Leeds laboratories. Previous experience in determining the density of radon by means of a Steele and Grant microbalance led him to the development of a buoyancy microbalance capable of high accuracy in which constancy of zero was ensured by a torsion fibre suspension. With this instrument the limiting densities of xenon, carbon monoxide, carbon dioxide, ethylene, carbon tetrafluoride, methyl fluoride, silane, nitrous oxide and hydrogen sulphide were determined, and values for the atomic weights of carbon, fluorine, nitrogen, sulphur and silicon obtained which are independent of stoichiometric relationships. This work with gases containing carbon first brought to light an error in the atomic weight of carbon which, prior to 1933, was accepted by the International Committee as 12·00. The mean value found at Leeds was 12·011, which has been amply confirmed since by modern stoichiometric determinations and also by mass-spectrographic evidence. In these and other ways, Whytlaw-Gray has built up an influential research school at Leeds, and well and truly carried on the tradition of his distinguished teacher, Ramsay. He has never rested on his achievements, although these have received universal recognition. Ripening experience has, in his case, resulted rather in more devotion to experimental work and to its stimulation in others. It is a source of great satisfaction to his colleagues that he is to continue his investigations in the Department of Inorganic and Physical Chemistry at Leeds.

Prof. M. G. Evans and Prof. E. G. Cox

WITH the retirement of Prof. Whytlaw-Gray, the Council has decided to unite the hitherto separate Departments of Inorganic and Physical Chemistry. The combined Department will have two professors, of whom Prof. M. G. Evans, professor of physical chemistry in the University since 1939 (see *Nature*, July 1, 1939, p. 15), will be the senior. Dr. E. G. Cox, reader in chemical crystallography in the University of Birmingham, has been appointed to the second chair in the Department. For several years Dr. Cox has been on leave of absence to undertake highly specialized and secret work in the Government service, and has had charge of a laboratory. Latterly he held the rank of lieutenant-colonel on the staff of the B.L.A. in Europe. Dr. Cox is well known as one of the ablest experimenters in X-ray crystallography. His researches in the carbohydrate field, and also in connexion with co-ordination compounds, have won for him a high place as an investigator in structural chemistry. Graduating with first-class honours in the University of Bristol some twenty years ago, he proceeded to the Davy Faraday Laboratory at the Royal Institution and became a pupil of Sir William Bragg. From there he was appointed to a lectureship in physical chemistry in the University of Birmingham, and has been associated with Prof. W. N. Haworth in constitutional work on sugars and polysaccharides. One of his most notable researches was on the structure of vitamin C.

Penicillin Production in Great Britain

ON September 20, Glaxo Laboratories, Ltd., Greenford, Middlesex, gave a demonstration of the preparation of penicillin and showed the factory operation of freeze-drying and other processes through which the finished product goes; Sir Cecil Weir, director-general of equipment and stores, Ministry of Supply, was present. Sir Cecil said that during the War when key installations were open to enemy attack, it would have been wrong to give information about the location of factories concerned; but now it is possible to disclose that the production of penicillin is under way, or about to commence, in twelve factories in Britain, operated by eight firms well known in the pharmaceutical field or in fermentation processes. Britain will soon have in operation the largest penicillin production unit in the world at Speke, and one of the largest at Barnard Castle; the latter is to be run by Glaxo Laboratories, and will make four for which the firm is responsible.

As soon as it became evident in 1942 that factory production of penicillin was feasible, the Ministry of Supply brought together potential manufacturers and scientific men, and the present results are due to the team-work thus initiated. As British resources in building and operational labour, as well as scientific and technical staff, were fully extended, it was not expected that progress would be so rapid in Britain as in the United States, but close touch was maintained on the subject between the two countries. Britain has shared with the United States for military purposes the greater production which that country was able to obtain during the War; but it will not be long before Britain is producing penicillin on a comparable basis. The history of penicillin production during the War has much in common with that of the atomic bomb; in both cases production was undertaken in the United States on account of the greater facilities available and the freedom from bombing. Sir Cecil also referred to recent references in the Press to the possibility that penicillin may become infected in the course of manufacture. This danger always exists in fermentation processes, particularly in the early development of a new factory, but, as was to be seen at the Glaxo Laboratories, the manufacturers take every precaution to maintain sterility; and there is no ground for any suggestion that a great deal of penicillin is unfit for use.

Folk-Lore of Toothache

In a recent article on this subject (*Brit. Dent. J.*, **78**, 226 and 257; 1945), forming the quinquennial Wallis Lecture and read before a conjoint meeting of the Sections of Odontology and History of Medicine of the Royal Society of Medicine, Dr. J. D. Rolleston said that the abundance of dental folk-lore was shown by the numerous books and articles, of which the best known in alphabetical order were those of Baldinger, Bremner, Guerini, Haber, Kahn, Kanner, Lindsay, Lufkin, Sudhoff, Taylor, Townend and Weinberger. Owing to the extensive character of dental folk-lore, Dr. Rolleston confined himself to its most prominent aspect, toothache, and no reference was made to the superstitions of normal dentition, the discoloration and mutilation of the teeth in savage races, the legend of the Golden Tooth, the toothpick and the toothbrush and the various aspects of dental surgery, apart from a brief allusion to filling and extraction.

There are numerous examples of the transfer of toothache to other persons, as can be seen from Sir James Frazer's volume of the "Golden Bough" entitled "The Scapegoat". Hydrotherapy for toothache was instanced by the large number of wells believed to cure toothache, especially in Scotland, the Palatinate and Upper Austria. Charms against toothache date back for many centuries, the earliest of the kind having been found in the Babylonian legends of 4000 B.C. During the Middle Ages, charms, which are the most popular of toothache remedies, were sometimes spoken, but were more frequently inscribed on paper, parchment, wood or stone, and were hung round the patient's neck or loins. Professional charmers have existed until modern times. Patron saints play an important part in the folk-lore of toothache, as they do in that of other diseases. The chief patron saint of dentistry is St. Apollinaria, who died a martyr in A.D. 249, whose memory is kept alive by relics and pilgrimages in various European cities and in Britain. Besides St. Apollinaria there are more than twenty saints supposed to relieve or cure toothache.

The Night Sky in October

New moon occurs on Oct. 6d. 05h. 22m., U.T., and full moon on Oct. 21d. 05h. 32m. The following conjunctions with the moon take place: Oct. 3d. 12h., Venus 4° S.; Oct. 27d. 05h., Mars 0·8° S.; Oct. 27d. 05h., Saturn 2° S. In addition to these conjunctions with the moon, the following conjunctions take place: Mars in conjunction with Saturn on Oct. 26d. 07h., Mars 1·4° N.; Venus in conjunction with Jupiter on Oct. 30d. 08h., Venus 0·5° N. No occultations of stars brighter than magnitude 6 take place during the month. Mercury is in superior conjunction with the sun on Oct. 2 and is unfavourably placed for observation during the month. Venus is a morning star, rising at 3h. 12m., 3h. 56m., and 4h. 45m., at the beginning, middle and end of the month respectively. Mars, in the constellation of Gemini, rises at 22h. 08m. on Oct. 1 and at 21h. 15m. on Oct. 31. Jupiter, in conjunction with the sun on Oct. 1, rises an hour before the sun at the middle of the month and a little more than two hours before the sun at the end of the month, and can be seen in the morning hours. Saturn, in the constellation of Gemini, rises at 23h. 07m. on Oct. 1 and at 21h. 15m. on Oct. 31. The Orionid meteors are due about the third week in October, but moonlight will partly interfere with observations of this shower.

Announcements

Messrs. Coventry Gauge and Tool Co., Ltd., Taylor, Taylor and Hobson, Ltd., and E. R. Watts and Son, Ltd., have agreed to co-operate in the development and distribution of precision engineering and optical equipment. They will pool their technical and manufacturing resources for the development of new instruments, while the sales and service departments will handle the products of all three firms.

It is announced that a catalogue of all the medical films in Great Britain is now being prepared by the Royal Society of Medicine in co-operation with the Scientific Film Association. It would be appreciated if any persons having films of medical or para-medical interest, who have not already been asked for details, would communicate with the Film Cataloguer, Royal Society of Medicine, 1 Wimpole Street, W.1. By so doing they would not commit themselves or their films, but would enable the catalogue to be complete.

The National Cancer Institute at Bethesda, Maryland, has undertaken to compile and publish all the data available relative to cancer therapy. All types of therapy except surgery and irradiation will be covered. Negative and positive results of the treatment of spontaneous, transplanted and induced experimental tumours, and of clinical cases, will be included. The data will be classified and tabulated in a simple manner similar to that in Hartwell's "Survey of Compounds Which Have Been Tested for Carcinogenic Activity" (National Cancer Institute, 1941). Reprints of published work in this field or any unpublished results which may be used should be sent to Prof. Helen M. Dyer, National Cancer Institute, Bethesda 14, Maryland, U.S.A.

The Electrical Association for Women is marking its twenty-first anniversary by an exhibition, arranged by the British Electrical Development Association, at the Dorland Hall, Lower Regent Street, London, S.W.1, during October 11–25. The exhibition will be opened by the Duchess of Kent, and at the following luncheon Sir Stafford Cripps will speak. On October 12 there will be addresses by Sir Robert Watson-Watt, Dr. Kathleen Lonsdale and Sir Harry Railing. The Women's Engineering Society, the body from which the Electrical Association for Women arose, is holding its annual conference during October 12–13; Miss M. M. Partridge will give the presidential address on "The Next Twenty-one Years".

Erratum. In *Nature* of September 22, p. 371, col. 1, line 23, for "the production of gas from sulphur" read "the production of gas almost free from sulphur".

A New Test for 2 × 2 Tables

UNDER this heading, G. A. Barnard[1] puts forward a test which, in language adopted from Neyman and Pearson, "is more powerful than Fisher's". This means in practice that the test advocated passes as significant certain classes of experimental result which, by the test I had put forward[2], would have been judged insignificant; and that, as judged by Barnard's method, my test is thought to be too stringent. However one may choose to express it, the cause of the difference in these calculations is worth elucidating, and, in taking the view he does, Barnard is following the very distinguished precedent of Prof. E. B. Wilson, whose similar proposal a few years ago[3] led to some clarification of the issue[4,5,6].

In the treatment of the problem for which I am responsible, all possible fourfold tables are classified according to the marginal distributions they exhibit. Thus in the case considered by Barnard in which, using three experimental and three control animals, the experimental animals all die and the control animals all survive, the two marginal distributions are both specified by the partition (3^2). Subject to this restriction, only four different experimental results are possible, symbolized by

$$\begin{array}{c|c}3&0\\\hline 0&3\end{array}\qquad\begin{array}{c|c}2&1\\\hline 1&2\end{array}\qquad\begin{array}{c|c}1&2\\\hline 2&1\end{array}\qquad\begin{array}{c|c}0&3\\\hline 3&0\end{array};$$

and I have demonstrated that, *whatever may be the probability of survival*, if it is the same for both lots, the probabilities of these four possible outcomes are in the ratio 1 : 9 : 9 : 1; or, in other words, the probability of obtaining the most successful outcome by chance is always 1 in 20. For any other marginal distributions a similar series can be obtained, but with these even the most favourable outcome has so high a chance probability that in no case could it be judged significant. It is my view that the existence of these less informative possibilities should not affect our judgment of significance based on the series actually observed.

It may, however, be demonstrated that with repeated sampling, using always three experimental and three control animals having the same probability of death, such outcomes will often occur. If it were legitimate to judge the level of significance from the proportion of significant judgments in the whole series of 'repeated sampling from the same population', these cases would be brought in to inflate the denominator of the fraction. The least possible frequency of these other series occurs when the chance of death is $\frac{1}{2}$ for both groups, and, in the aggregate, they will then occur 44 times to 20 occurrences of the series observed. Thus Barnard's argument leads to the conclusion that the acceptance of the result as significant is at the significance level 1/64 rather than 1/20; or, more properly, that it has some unknown value not greater than 1 in 64.

In my view the notion of defining the level of significance by 'repeated sampling of the same population' is misleading in the theory of small samples just because it allows of the uncritical inclusion in the denominator of material irrelevant to a critical judgment of what has been observed. In 2 of the 64 cases enumerated above, all animals die or all survive. The fact that such an unhelpful outcome as these might occur, or must occur with a certain probability, is surely no reason for enhancing our judgment of significance in cases where it has not occurred; any more than the possibility that a breeding experiment might have yielded too few offspring to allow one to draw any significant conclusion should not enhance our judgment of significance whenever there are enough offspring for the significance of any supposed effect to be worth discussing.

Of course, the notion of repeated sampling from the same population is usually taken to imply that the total size of the sample is fixed. The total size does not, however, always suffice to specify the type of sample which has been obtained, and it is only the sampling distribution of samples of the same type that can supply a rational test of significance.

A Classical Theory of Electromagnetism and Gravitation

ATTEMPTS to obtain a unified theory of gravitational and electromagnetic phenomena[1] have assumed the form of generalizing the equations of general relativity theory, so that they incorporate terms which may be identified with electromagnetic potentials and charge and current distributions. At the moment it seems that these attempts will not lead to an explanation of such quantum theoretical results as the indeterminacy principle, and their very complexity makes it difficult to see how they will yield a hint as to necessary modifications of the equations of quantum theory required to overcome the difficulties inherent in its present form. In any event, such a synthesis of gravitational and electromagnetic phenomena in quantum theory is generally regarded as secondary in importance, since gravitational forces on elementary particles are extremely small.

It seems of interest, however, to return to the classical theory and look for a simple set of equations which give simultaneously a relativistically covariant theory of gravitational and electromagnetic phenomena. For regions of space occupied only by charge and current distributions, the Maxwell-Lorentz equations

$$\frac{\partial f_{\nu\sigma}}{\partial x_\mu} + \frac{\partial f_{\sigma\mu}}{\partial x_\nu} + \frac{\partial f_{\mu\nu}}{\partial x_\sigma} = 0,$$

$$\frac{\partial f_{\mu\nu}}{\partial x_\nu} = \frac{4\pi}{c}\, i_\mu, \quad k_\mu = \frac{1}{c}\, f_{\mu\nu} i_\nu \quad . \quad . \quad (1)$$

give a very satisfactory system of Lorentz covariant equations for the determination of either the electromagnetic field produced by a given charge distribution or the behaviour of a charged body in such a field. The equations are simplified if the Lorentz condition

$$\frac{\partial A_\nu}{\partial x_\nu} = 0 \quad . \quad . \quad . \quad . \quad . \quad (2)$$

be applied, where

$$f_{\mu\nu} = \frac{\partial A_\nu}{\partial x_\mu} - \frac{\partial A_\mu}{\partial x_\nu}.$$

In these equations gravitational forces do not appear, and it is usual in classical theory to treat problems involving gravitational potentials separately. The original theory of Kaluza is based on the introduction of an extra dimension, of no physical significance. We therefore consider the above equations (1) and (2) when we allow the suffixes to assume the values 1 up to 5. Writing $A_5 = -\Omega$, $i_5 = c\sigma_0$, $x_5 = R$, we are led to the equations

$$\nabla \cdot \mathbf{A} + \frac{\dot{\phi}}{c} - \frac{\partial \Omega}{\partial R} = 0 \quad . \quad . \quad . \quad . \quad (3)$$

$$\left(\nabla^2 - \frac{1}{c^2}\frac{\partial^2}{\partial t^2} + \frac{\partial^2}{\partial R^2}\right) \begin{matrix} \mathbf{A} \\ \varphi \\ \Omega \end{matrix} = -4\pi \left| \begin{matrix} i/c \\ -\rho \\ \sigma_0 \end{matrix} \right. \quad . \quad . \quad (4)$$

$$\left.\begin{aligned} \mathbf{k} &= \mathbf{E}\rho + \frac{1}{c}(\mathbf{i} \times \mathbf{H}) - \sigma_0 \nabla \Omega - \sigma_0 \frac{\partial \mathbf{A}}{\partial R} \\ cW &= \mathbf{i} \cdot \mathbf{E} + \sigma_0 \dot{\Omega} - c\sigma_0 \frac{\partial \varphi}{\partial R} \end{aligned}\right\} \quad . \quad (5)$$

$$\nabla \cdot \mathbf{i} + \dot{\rho} = -c \frac{\partial \sigma_0}{\partial R} \quad . \quad . \quad . \quad . \quad (6)$$

Equations (5) suggest that σ_0 may be identified with the rest density, and Ω with the gravitational potential. Since σ_0 is invariant for rotations of the axes $x_1 \ldots x_4$, the result arises that gravitational force per unit volume is exerted only on the rest-mass density, and not on the increased density arising from a possible velocity of the matter relative to the observer. If we set $\frac{\partial}{\partial R} \equiv 0$, the equations are applicable to flat space-time, and gravitational waves are seen from (4) to be propagated with the velocity of light. In agreement with the generalized unified theories, equation (6) shows that charge is conserved only for flat space-time.

It does not seem reasonable that the extra dimension R should be singled out for special attention, and in general the gauge is shown from (3) to be simply connected with the rate of change of the gravitational potential in this extra direction. We may attach physical significance to R if it is noted that the radius of curvature of space-time at a particular point is different for observers accelerated with respect to each other. We therefore postulate that to an observer S_0 falling freely under the influence of the local gravitational field, space-time in his immediate neighbourhood appears flat, and we may set $\frac{\partial}{\partial R} \equiv 0$. To an observer S accelerated with respect to S_0, the same space appears to have a finite principal radius of curvature R. From these assumptions a simple generalized theory of transformations may be developed to compare the observations of observers accelerated with respect to each other, in the same way that the theory of Lorentz transformations yields the results of the special theory of relativity.

Details of the theory will be published later.

Cosmic Rays and Kinematical Relativity

I admit (indeed, I insist on) Prof. Haldane's claim[1] that kinematical relativity would be justified in substituting another "equally valid" cause of the red-shift for relative motion; my point is that it has not done so. In my letter[2], I named all the causes (I do not insist on this terminology if Prof. Haldane can think of a simpler and equally clear one) I could think of, and Prof. Milne chose[3] relative motion. It was then that I repeated the objection Prof. Haldane has quoted. If he prefers a different choice from Prof. Milne's, I will repeat the objection to that. It is, however, futile to run from one untenable explanation to another, like a squirrel in a cage.

The basic objection to Prof. Milne's theory is that it allows the distance between Prof. Haldane's nose and the lamp-post to remain constant at what it was, say, one minute before impact, in spite of the fact that his nose is broken. It will concentrate the whole problem into a single point if Prof. Haldane will state how he accounts for his disfigurement, and how he dates subsequent events, on the time-scale which keeps the lamp-post a constant distance away.

I am not sanguine of the possibility of convincing Prof. Milne by a *reductio ad absurdum*. Deductions concerning stellar evolution are apt to become 'verifiable' in a few billion years time. In the meantime, I believe I have reduced the fundamental principle, not merely a particular application, to absurdity by the argument now under discussion; but Milne refuses to regard this as a blemish because I have not indicated a flaw in his voluminous mathematics[3]. He will not recognize that an absurdity can follow from false premises even though (indeed, because) the connecting mathematical argument is faultless. Hence I do not expect that any difficulty connected with what is presumed to have happened a thousand million years ago will convince him that he is following a will-o'-the-wisp.

As regards cosmic rays, Milne's theory of this phenomenon[4] requires space to be filled with particles moving faster than light; but he gets around this by saying that such particles would be unobservable. I pointed out some time ago[5] that such particles, if they existed, must be constantly hitting stars, and since their momentum would be infinite the consequences would not be unobservable. No reply has been made to this. So much for the hopes of a test of the theory arising from "agreement or disagreement with fact of calculations concerning cosmic rays".

Interaction of Aluminium Halides with the Xylenes

Recently[1], it has been suggested that the study of equilibria between the aromatic hydrocarbons[2] in the presence of aluminium halides might be complicated by the formation of stable complexes between the aluminium halide and some of the hydrocarbons. If, as has been shown[1], the heat of complex formation varies considerably with different hydrocarbons, then the composition of the equilibrium mixture of free hydrocarbons will be different from the composition of the mixture of hydrocarbons in the complex. This may lead to uncertainty in the equilibrium concentrations of hydrocarbons, if, as in much of the experimental work described in the literature[2,3], only the total hydrocarbon, including both the free hydrocarbon and that obtained by decomposing the complex, is analysed, since this may result in equilibria which appear to vary with the ratio of aluminium halide to hydrocarbon. Some recent exploratory experiments of ours are of interest in this connexion.

At equilibrium, the system aluminium halide and xylene separates into two phases: (*A*) a supernatant, pale brown, mobile layer which contains only a trace of aluminium halide; (*B*) a more dense, very dark brown, viscous layer which contains most of the aluminium halide. This latter layer can be separated, as has been suggested by Norris and Rubenstein[4], into two fractions: (*B*1) a colourless hydrocarbon layer containing no aluminium halide, which is separated from the non-volatile fraction *B*2 by vacuum distillation at 20° C.; and (*B*2) a very dark, very viscous residue which, when carefully decomposed with water at 0° C., gives an almost colourless hydrocarbon mixture.

In the present work, these three fractions (*A*, *B*1, *B*2) were distilled in vacuum at 20° C., washed with dilute caustic soda and then water, and dried with calcium chloride. The compositions of the fractions were determined from their ultra-violet spectra, since aromatic hydrocarbons have characteristic spectra in this region. The absorption spectra of 0·5 per cent solutions by volume of these fractions in spectroscopically pure *cyclo*hexane were photographed using an absorption path-length of 1·8 mm. The starting materials were either a *meta-para* xylene mixture (approximately 4 : 1) or an *ortho-meta* mixture (approximately 95 per cent *ortho*), and these were equilibrated at 20° C. and at 60° C. with aluminium chloride.

Inspection of all the photographs suggested: (1) Fraction *B*2 is always different from *A* and different from *B*1. (2) *B*1 is, in all cases, very nearly the same as, or possibly identical with, *A*. (3) *B*2, formed when starting with the *ortho-meta* mixture, is not the same as when the *meta-para* mixture is used. In the latter case, *B*2 is almost entirely pure *meta*-xylene. There is no evidence that *B*2 is in true thermodynamic equilibrium. (4) Starting with the *meta-para* mixture, true equilibrium appears to be reached in the fraction *A*, since no variation of the composition with time has been found. This is in general agreement with Pitzer and Scott[2]. (5) Starting with the *ortho-meta* mixture, fraction *A* does not appear to reach equilibrium although longer times were employed than in (4). This may be due to: (i) the reaction having further to go to reach equilibrium when the starting material is largely *ortho*; (ii) the complex formed from *ortho* is different from that from *meta* and may not be so active catalytically; (iii) side reactions may become important when starting with *ortho*; our analyses cannot exclude the presence of toluene after reaction, although benzene is certainly absent. (6) In the reaction starting with the *ortho-meta* mixture, aluminium bromide behaves qualitatively similarly to the chloride.

These results show that the system is very complicated, and, although much more work must be done before the system is completely understood, the following picture appears to be qualitatively correct. At equilibrium, the system aluminium chloride and xylene forms two immiscible liquid phases, one of which is a very dilute solution of the aluminium chloride complex in the normal equilibrium hydrocarbon mixture, and the other is a mixture of the complex and the normal equilibrium hydrocarbon mixture. The composition of the hydrocarbon mixtures in the complex and in the free state is always different. Before a picture of aromatic equilibria can be completed, a detailed analysis of all possible separate phases is essential.

One of us (E. F. G. H.) wishes to thank the Director of Fuel Research for permission to publish this communication.

A Sexual Reproduction Cycle of *Trypanosoma congolense* Broden

DURING the course of work on the destruction of trypanosomes by phagocytes in the blood of cattle, gamete forms of *Tryp. congolense* were observed in thick unfixed blood smears, both paired and unpaired.

This phenomenon, at first thought to be an appearance caused by staining with Giemsa of unfixed blood preparations, was studied, and developmental forms were found in Giemsa-stained smears and sections from the skin of infected cattle. *Tryp. congolense* was then stimulated to conjugate by addition to a drop of heavily infected mouse blood of a drop of hypotonic saline solution (0·3 per cent sodium chloride), and the actual conjugation was seen under the microscope. This technique, though possibly unsuitable for a morphological study of trypanosome forms, is convenient, since the process of conjugation can be studied with ease, owing to hæmolysis of most red blood cells. It is not, however, constantly seen, and it may be supposed that mature gametocytes are not always present.

In mouse blood, treated in this way, trypanosomes are not fatally injured, though the adult form is distended. Sexually mature forms quickly become micro- and macro-gametes and conjugate within ten minutes. The micro-gamete is 6–9 μ in length and the nucleus becomes posteriorly placed, with the rest of the body an attenuated filament; macrogametes are 13–19 μ in length, with the nucleus somewhat anteriorly placed, both nucleus and cytoplasm being intensely granular, except for a swollen area posteriorly which is clear and translucent. The posterior end of the microgamete enters the translucent posterior area of the macrogamete, and the microgamete is absorbed.

A motile zygote is formed, of trypanosome form, but tapering from the posterior end. Nuclear material is next concentrated centrally or posteriorly, and by contraction of other parts of the body an amorphous oocyst is formed. The oocyst nucleus may after sixty minutes have divided once. The zygote is about 20 μ in length, and oocyst about half this size.

Oocysts have been found in skin sections and in the lung of one calf, which was successively exposed to cold at 4° C., in order to occlude the skin capillaries and drive the trypanosomes into the general circulation. Oocysts have also been studied in skin smears on supravital slides (neutral red) kept moist by addition of a drop of normal bovine serum. The oocyst appears to form sporoblasts, probably eight, which divide into innumerable sporozoites. The sporozoites break away from the oocyst body and swim actively away by a kind of rolling movement.

The fate of the sporozoite is uncertain. It is initially about 1–2 μ in diameter and its morphology has not been fully determined. It is probably leishmannioid, since larger forms have been seen of this type. It does not aggregate or develop in the tissues, though skin smears reveal developmental forms—leptomonad, crithidial and immature trypanosome. It is suspected that the macrophages are parasitized, since in skin, lymphatic gland and kidney sections, these cells have been found containing bodies, the larger of which are leishmannioid in appearance.

Trypanosomes treated with hypotonic saline in mouse blood react in three different ways and are plainly of three different forms as follows:

(1) Immature sexual or asexual. These become swollen by the saline, but show no other changes, though some may conjugate after forty-five minutes. (2) Mature sexual forms, which conjugate as described. (3) Infective (?) forms, which become changed into a variety of developmental types, usually associated with life in the tsetse fly, such as round forms, stumpy forms, elongated forms and so on.

These matters will shortly be described at greater length in a preliminary communication, and a full report published when all details have been studied.

Multiplication *in vitro* of Koch Bodies of *Theileria annulata*

The following simple method modified from Jacoby (1944) was found suitable for the growth *in vitro* of *Theileria annulata*. A small fragment of infected calf's spleen or lymphatic gland is placed on a sterile glass coverslip and a drop each of calf plasma and chickens' embryonic extract are added. After coagulation the coverslip is sealed to the bottom of a large Carrel flask by a drop of plasma and embryonic extract; 3–5 c.c. of a mixture of 30–40 per cent calf serum in Tyrode is then added and the flask closed and incubated. On this medium Koch bodies survive for at least twelve days, but do not multiply. If fragments of normal spleen are placed in juxtaposition to the infected fragment at intervals of 3–5 days, Koch bodies survive for 15–18 days, but there is no obvious multiplication. The addition of glutamine (3 γ per c.c.), pyridoxin (0·6 γ per c.c.), inositol (4 γ per c.c.) and riboflavine (0·04 γ per c.c.) to the mixture of serum and Tyrode induces multiplication of Koch bodies, which was observed in ten successive fragments of normal calf spleen during a period of two months. The addition of these factors to the transplant, in which Koch bodies have survived without multiplication for eighteen days, immediately induced multiplication of the surviving parasites.

It is interesting to note that, *in vitro*, good growths are obtained in spleen fragments of recovered animals and overlying fluid containing 40 per cent of serum of the same animals. *In vivo* massive inoculation of infected blood or macerated infected lymph glands do not produce an attack of theileriosis in recovered calves, which always harbour a residual infection.

I have to thank Prof. Adler for his advice and Dr. Grossowitz for his kind help.

Histological Fixation of Locomotory Patterns

Normal histological methods usually fail to yield a satisfactory picture of the shape and form of a muscle at any given phase of its activity. For such purposes the following technique has been found useful in the case of small terrestrial or aquatic animals. Absolute alcohol is cooled to about −117° C. by submersion in liquid air. Small terrestrial animals moving over fine wire gauze or thin aluminium foil are quickly dipped into the alcohol, and aquatic animals moving in a small quantity of water contained in a spoon of aluminium foil are treated likewise.

Fixation for histological investigation can be achieved in a number of different ways, according to the material used; for example, dehydration in a frozen condition, gradual thawing in alcohol plus formic acid, etc.

Animals investigated so far include Planarians, Nemertines, Annelids, Gastropods, Myriapods, and small vertebrates. Fixation appears to be instantaneous; the tentacles of snails and slugs remain protracted, and the locomotory waves are clearly recognizable. The setæ protrude in the longitudinally contracted segments of an earthworm, and are retracted in the elongated segments.

The details of the method will be discussed elsewhere. It is hoped that it may help to correlate, more satisfactorily than has been possible hitherto, structure and function within the animal body.

A Modification of Slide-Culture Technique

A very simple and effective method of making slide-cultures for the study of moulds is described below. It has many advantages over the methods described by Henrici[1] (p. 30), Lewis and Hopper[2] (p. 221), Langeron[3] (p. 957), and Smith[4] (p. 176). The procedure, a slight modification of existing methods of slide-culture, was worked out by M. C. White and me jointly, while attached to the laboratories of the South African Institute for Medical Research, Johannesburg, on military duties.

Sterile nutrient agar is melted in a culture tube, in a water bath, and allowed to cool down to between 40°–45° C. This is inoculated fairly heavily with spores of the mould to be studied taken from a pure culture. A very small drop of the inoculated agar is transferred to a flamed slide by means of a platinum loop and is immediately covered over with a flamed coverslip. It should be noted that a hollow-ground slide is not employed. The agar drop must be of such a size that when the coverslip is gently pressed flat the agar occupies a circle about half the diameter of that of the coverslip.

The slide-culture is incubated in a petri dish, in the bottom of which are a few layers of wet filter paper, the whole having previously been autoclaved. Suitable glass supports raise the slide well above the level of the wet paper. During incubation it is important that the paper should not dry out, and sterile water should be added periodically if necessary. Smith[4] (p. 176) recommends the use of a 20 per cent solution of glycerol instead of water, as the latter tends to wet agar.

On incubation the mycelium spreads rapidly through the agar, and hyphæ and sporophores then grow out into the airspace under the coverslip. When a suitable growth has occurred, usually after three or four days, the preparation may be made into a semi-permanent mount by introducing Shear's mounting fluid, with or without added stain, under the coverslip. Air bubbles which are formed are easily removed by placing the preparation in a jar, which is then evacuated by means of a vacuum pump. More durable preparations can then be made by ringing the coverslip with any of the usual ringing cements.

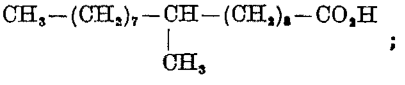
Fatty Constituents of Tubercle Bacilli as Growth-inhibitors of the same Bacilli

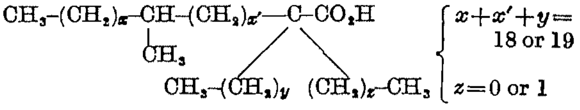
A MOST valuable clue in the search for bactericidal compounds has recently been found in the so-called 'antagonism principle' between bacterial vitamins and similarly built molecules of 'antivitamins'[1]. In the field of tuberculosis, this principle is unfortunately of little interest, as the bacilli responsible for this disease seem to need no vitamins for their growth. But an antagonism may be conceived to arise between plastic constituents of tubercle bacilli and substances with very closely related molecular structure, so that such substances can replace the former in the cellular frame without being able to exert any of the necessary vital functions.

Attempting to approach the problem of chemotherapy of tuberculosis from this point of view, I have studied the substitution of a naturally occurring chemical function by an 'unbiological' one, in the very molecules of some constituents of tubercle bacilli. Anderson, Chargaff, Robinson and others[2] have shown that these bacteria contain a fairly high proportion of numerous fatty acids that have not been encountered yet in any other living cell. Only two of these acids have been characterized with sufficient chemical accuracy (the tuberculostearic (I) and the phtioic acids (II)); but it has become clear now that many others are also highly branched-chain molecules. Employing Anderson's method, a mixture of such fatty acids was isolated from the dead bacilli of a virulent stock of human origin, and distilled in cathodic vacuum to remove the fractions of too high molecular weight, as well as any traces of waxy alcoholic acids. It was converted then, through the acid chlorides and the amides, into a mixture of primary amines, using a slightly modified Jeffreys' method. Whereas the initial material and the amides are practically inactive, the mixture of amines so obtained (in form of the hydrochlorides) proved itself to be strongly bacteriostatic against tubercle bacilli growing on synthetic media (at such high dilutions as 1/10,000 and more). Hence it is clear that a naturally occurring substance endowed with vital properties may be changed into a specifically toxic material through the single replacement of a carboxyl by an amino-group. It is noteworthy that synthetic fatty amines such as (III), prepared from higher fatty amides following Montagne's process[3], also exhibit more or less bacteriostatic properties against acid-fast bacteria.

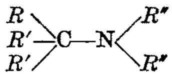


$$CH_3-(CH_2)_7-\underset{\substack{|\\ CH_3}}{CH}-(CH_2)_8-CO_2H \quad ;$$

(I)



(II)



(III)

Work is in progress in this field, and also to ascertain whether the amidine-group may be of use for the same purpose. But it is perhaps worth while stressing the fact that such an *in vitro* conversion of the constituents of a bacterium into an inhibitor, through the modification of a radical while maintaining the molecular configuration, forms a bridge between chemotherapeutic methods and immunological ones.

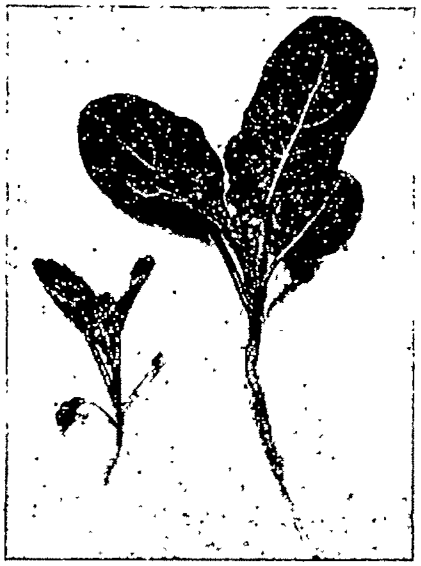
A Case of Molybdenum Deficiency in New Zealand

IN a small private-garden investigation into the disease 'whiptail' of cauliflowers, extreme symptoms appeared in those plants not treated with the group of trace elements manganese, zinc, copper and molybdenum. The matter was therefore studied more closely in the glasshouse. In an experiment involving some twenty combinations of two and three of the elements manganese, zinc, copper, molybdenum and



COMPARISON OF MOLYBDENUM-DEFICIENT AND HEALTHY CAULIFLOWER SEEDLINGS. *Photo: S. A. Emmerson.*

boron with and without lime, and in which phosphate, potash and nitrogen were adequately provided, 'whiptail' failed to develop. At an early stage of growth, however, all plants not supplied with molybdenum developed an intervenal chlorosis very similar to that described by Arnon and Stout[2] in molybdenum-deficient tomatoes. The symptoms were much more pronounced where lime had been omitted. This is in line with a body of evidence[5,7,8,11,12] that soil molybdenum is more available for plant uptake in limed or naturally alkaline soil. The unlimed plants in particular also showed the involution of the leaf edges and marginal necrosis seen in the tomatoes. The addition of sodium molybdate to the soil brought about a rapid recovery of the affected plants. No marked growth differences were associated with the symptoms, and eventually all plants grew out of the condition. The habit of the plants was not normal in the glasshouse and they were not left to reach maturity.

The characteristic leaf distortions of 'whiptail' could very well be caused by a check in growth of the leaf margins. A further small experiment was therefore carried out *in situ* to see if under natural conditions molybdenum might not prove the critical factor. Treatments with and without added molybdenum were compared, phosphate, potash and nitrate being supplied in each case, but no lime. The rate of application of molybdenum (3 lb. of sodium molybdate per acre) may have been a little high, as some germination injury occurred. The contrast between the two treatments was most striking; the plants without molybdenum being chlorotic and making very little progress, while those with the addition were vigorous and dark green in colour. The characteristic mottling was not evident until some growth had been made, the young plants showing a more general chlorosis.

At the present stage, 'whiptail' appears to be developing in some plants of both treatments, and the deficiency described may have no connexion with the disease. 'Whiptail' is usually stated as occurring on very acid soils and as being controlled by heavy liming[3,9,13]. One instance has been described, at Mickleton, Gloucestershire, on a soil containing free lime.

The soil worked with is an unusually acid phase of Ngaio silt loam (pH 4·7, percentage saturation 35), and the strain of cauliflower Southern Cross.

Molybdenum deficiency has been shown to occur in South Australia[1] and Tasmania[4,5,6,12]; but this is the first instance demonstrated in New Zealand.

Calomel and Onion Eelworm

MOSLEY has recently suggested[1] that, by liberally dressing onion seed with calomel, control may be obtained not only of onion fly and onion white rot but, possibly, also of the onion eelworm, *Anguillulina dipsaci* (Kühn).

In order to test this, the following experiment was set up. Large numbers of quiescent, infective larvæ of *A. dipsaci* were available in the form of eelworm 'wool' obtained from narcissus bulbs in October 1944. The nematodes in this state revive on being moistened and swim freely in water, and it is in this stage that I have shown that they may occur attached to the outside of commercial samples of onion seed[2]. Preliminary tests showed that the eelworms readily revived from the 'wool' when placed in water; the material was thus quite suitable for the intended tests.

Small portions of it a few millimetres in diameter, and each consisting of some hundreds of the parasite, were coated with finely powdered calomel and then placed in fresh garden soil contained in glass tubes 2 in. long by 1 in. wide. Each tube was half-filled with good rich kitchen garden soil. A piece of 'wool', well covered with calomel, was then inserted, and the tube was filled with more soil with the object of ensuring that, if the calomel decomposed in the soil, any of its decomposition products would be in intimate contact with the reviving eelworms. A drop of sterile water was added to each tube sufficient to moisten the soil. A tube without calomel was put up in exactly the same way to serve as a control. All the tubes were then set aside in a moist chamber on the laboratory bench and left for any action to take place. After the lapse of five, eleven and nineteen days, water extracts of the soil from the tubes were made by the Baermann funnel technique. This is a very simple and efficient method for obtaining eelworms from plant material and soil. A piece of rubber tubing is placed on the stem of a glass funnel and is closed by a pinchcock. The funnel is then partly filled with tap water to a convenient depth and clamped in an upright position. The material to be extracted, wrapped in a piece of cheese-cloth, is then gently submerged in the water and left for an hour or two. Living eelworms soon begin to wriggle out of the material and, sinking down through the water, collect in the stem of the funnel. By opening the pinchcock and running out some of the water into a Petri dish, eelworms can be searched for under the microscope.

In the extracts made in this way from portions of soil from the control tube and from calomel-treated tubes after five, eleven and nineteen days, large numbers of living *A. dipsaci* were obtained swimming freely in the water. The worms from the calomel tubes were just as lively as those from the control tube, thus indicating that the calomel, or its decomposition products, had had no lethal action on the worms reviving from the 'wool'. It seems improbable, therefore, that calomel is likely to prove of service for the control of the eelworm attached to onion seed. If its decomposition products do not destroy the parasite by the nineteenth day after contact (by which time the bulk of the seed in any good sample of onion seed would have germinated) its use as an effective control for seed-borne infections of the eelworm seems to be ruled out. I have determined that the parasite on onion seed can be completely controlled by the fumigation of onion seed with methyl bromide, which does not injure the seed but retards its germination slightly[3].

Control of Dry Rot of Seed Potatoes by Dusting

AT the present time, the only practicable method of controlling dry rot of seed potatoes (*Fusarium cœruleum*) is to dip the tubers immediately on lifting in a solution of one of the proprietary organo-mercury compounds prepared for the purpose[1,2]. This requires large numbers of boxes in which the tubers must be placed to dry—extra labour at an already busy season—since the toxic nature of the dip necessitates the removal of ware potatoes before treatment, and, in many cases, considerable outlay in plant. For these reasons, dipping seems suited mainly to the large specialist growers and not to the smaller farmers whose crops form the bulk of the tonnage concerned.

The wide adoption of any method of control of dry rot depends on (1) effectiveness, (2) absence of deleterious effect on the tubers, (3) ease of application, and (4) small capital outlay on plant. Only a dry treatment appears likely to fulfil all these conditions. In 1938, Dr. R. G. Tomkins, of the Low Temperature Research Station, Cambridge, suggested to one of us (C. E. F.) five volatile compounds which he considered worth testing. These were α-naphthol, thymol, diphenyl, 4 chlorophenylphenol and 2 : 5 dichloronitrobenzene. Peat was suggested as a suitable carrier. Preliminary experiments showed thymol to be the most promising of these, and large-scale trials with this compound have been carried out during the past three years on Scotch seed, under conditions approaching those found in commercial practice. Kaolin was used provisionally as a carrier after trials comparing it with peat and gypsum. The rate of application has been 12 oz. thymol, made up to 10 lb. with kaolin, per ton of potatoes. A single application, either on lifting or on riddling for dispatch to England in December or March, has been found to give somewhat variable results; but a double application, that is, both on lifting and on riddling, has been found to provide excellent control of the disease, on the average slightly better than that obtained with the standard single treatment with organo-mercury dip mentioned above.

CONTROL OF DRY ROT BY DUSTING WITH THYMOL KAOLIN. TUBERS TREATED 'AS GROWN' AND CLAMPED ON LIFTING · SEED RE-TREATED ON RIDDLING FOR DISPATCH TO ENGLAND.

Variety	Date dispatched	Dry rot per cent (April)	
		Untreated	Thymol kaolin
Catriona	December	17	1
Arran Pilot	December	46	1
Arran Pilot	March	19	5
Doon Star	December	31	4
Doon Star	March	32	3

These results, subject to confirmation by further trials planned for this season, indicate that the double treatment with thymol kaolin fulfils the first postulate of effectiveness. Unfortunately, however, it does not fulfil the second, as marked phytocidal effects on the tubers were noted in some of the experiments. The exact conditions governing the severity of the damage are not known; but burning has been found to be most severe on wounded surfaces and where tubers were kept in a humid environment after treatment. Immature tubers are thus more subject to damage because of their liability to skin abrasions. Varietal differences also occur; for example, Doon Star has been found to be much less susceptible to thymol injury than Arran Pilot and may be almost undamaged.

The third and fourth postulates, those of ease of handling and small capital outlay, are certainly covered, since dusting on lifting may be done by hand by a boy working with each collecting cart, while treatment on riddling could be accomplished automatically by means of a simple distributor placed over the bag chute. In addition—although further information on this point has still to be obtained—thymol might be considered sufficiently harmless to permit of treating both ware and seed, thus allowing the normal practice of clamping the crop 'as grown' when harvested.

Although the thymol dust cannot be advocated for commercial use unless its burning action can be overcome, the satisfactory level of control obtained shows that there are practical possibilities in the dry method of treatment.

RESEARCH ITEMS

New Genera and Species of Fishes

HENRY B. FOWLER describes two new genera and two new species in recent papers (*Notulæ Naturæ*, Academy of Natural Sciences of Philadelphia, "Description of a New Genus and Species of Apogonid Fish from New Jersey", No. 130, April 1944; "Description of a New Genus and a New Species of American Stromateid Fishes", No. 142, June 1944). The first, *Mimocubiceps virginiæ*, is of special interest, for, besides representing a new genus and species with interesting affinities, it introduces to the New Jersey fish fauna a family (Apogonidæ) not hitherto found within the limits of the State. This genus approaches *Erythrobussothen* Parr, but differs in many details. The second genus, *Simobrama*, is proposed for a harvest fish *Seserinus xanthurus* Quoy and Gaimard from Brazil, which is here redescribed, together with a related form, *Peprilus burti*, new species from the Gulf of Mexico.

Marine Cottid Fishes of California

IN a detailed review of the family Cottidæ, Rolf L. Bolin makes a most useful addition to the literature of the subject (*Stanford Ichthyological Bull.*, 3, No. 1; Oct. 1944). Almost one tenth of the marine fishes of California are members of this family, most of which live in tide pools or are shallow-water species. Identification hitherto has been very difficult and the present work will be a real help to ecologists, parasitologists and other biologists who are not specialists in ichthyology. There is an artificial key to the nineteen genera, each species is carefully described and the majority of them figured, keys being given for the species in many cases. The drawings of these fishes are exceptionally good.

Callianassidæ of the Central Pacific

UNDER this title Charles Howard Edmondson surveys the Callianassidæ taken mainly from the shallow reefs at Oahu, Hawaii (*Occasional Papers Bernice P. Bishop Museum*, Honolulu, Hawaii, 18, No. 2; 1944). Several species are described, the most interesting being a new species of *Callianassa* belonging to the subgenus *Calliactites* (*Callianassa* (*Calliactites*) *parva*), for the author has hatched out its larva. Hitherto no larva belonging to this sub-genus was known, and it is to be hoped that a detailed description of this peculiar form will be forthcoming in the near future. The larva differs from any known *Callianassa* larvæ in having no dorsal spine on the second abdominal somite and in having a thin spine-like rostrum instead of one that is broad, flat and toothed. The sixth abdominal somite is already formed and the telson is rounded posteriorly with only ten spines instead of the usual fourteen or more. The eyes are exposed and it may be that we have here a case of abbreviated development. Unfortunately the appendages are neither described nor figured. In his latest paper on this group, Gurney (*Proc. Zool. Soc.*, 114; 1944) gives six species the larvæ of which have been positively identified, four of which belong to the sub-genus *Trypaea*, one to *Cheramus* and one to *Callichirus*. Those belonging to the first two are of the same type and differ from the third, but none of these resembles the form here described. As the larvæ are probably an important guide to the relationships of the Callianassidæ a further description of this new species is much needed.

Examining the Functional Condition of the Liver

IN *Maroc-Médical* (Dec. 1944), J. Bailly and G. Decrop have an article with the title "A Propos D'Un Procede D'Exploration Simple De L'Etat Fonctionnel Du Foie", in which they describe minor modifications introduced into Pallardo's method for determining the state of the liver. Briefly, this method consisted in the administration of about 2·5 mgm. of a salt of quinine dissolved in a glass of water, and half an hour and an hour later samples of the urine are examined for the presence of quinine, tests being made by means of Tanret's reaction. In cases of absolutely healthy livers the quinine is completely disintegrated and hence does not appear in the urine. If, however, there should be any delay in the elimination of the quinine which has not been disintegrated, as often occurs, misleading results may be obtained, and Pallardo recommends the prolongation of the period of observation. Certain modifications in the method have been made by Bailey and Decrop because some unsatisfactory features accompany the tests advocated by Pallardo, among which may be mentioned Tanret's reaction. Their procedure is as follows. To 10 c.c. of the urine are added 10 drops of ammonia and then 10–15 c.c. of ether. After stirring the mixture and allowing it to stand for a time, the ether separates and floats on the underlying liquid which is drawn off, and the ether is transferred to a test tube. On adding 2 c.c. of $N/10$ sulphuric acid and stirring, the acid liquid is precipitated to the bottom of the tube and assumes a beautiful blue fluorescence if quinine is present. Results obtained from sixteen cases are given.

Germination of Bearded Iris Seeds

THE complexity of the factors affecting seed germination is illustrated in a study by L. F. Randolph and L. G. Cox (*Proc. Amer. Soc. Hort. Sci.*, 43, 284; 1943) on the germination of the seed of the bearded Iris (*Iris germica*). Cold storage of air-dry seed at − 2° to + 4° C. gave increased germination as compared with storage at normal temperatures, but high-temperature (35° C.) storage reduced germination, while alternating high and low temperatures were no more effective than low temperature alone. Wet storage of seeds increased the rate but not the final amount of germination. The importance of the seed-coat effect was shown by the fact that excised embryos in nutrient solution and embryos in contact with half the endosperm germinated more rapidly and to a greater extent than did intact seeds. Chipping of the seeds was not effective unless the cap of endosperm covering the radicle was removed, and the effect was further increased if the chipped seeds were leached in running water. Chipped, but not intact, seeds had their germination increased by additional oxygen.

Root Distribution of Fruit Trees

The failure of fruit trees to respond to fertilizer application may be due to a variety of factors. Sometimes either because of the soil character or the root distribution the added fertilizer fails to reach the absorbing roots. E. L. Proebsting (*Proc. Amer. Soc. Hort. Sci.*, 43, 1; 1943) summarizes studies on the root distribution of fruit trees in a well drained Californian orchard and shows that for cherries, almonds, apricots, peaches and prunes the maximum root concentration is between 2 ft. and 5 ft. deep. There are few roots at a greater depth and few in the surface foot (and these mostly at between 8 in. and

12 in.). In this case, root development nearer the surface is probably inhibited by high summer temperatures and when peach seedlings were grown in containers artificially heated by immersion in water, maximum root growth occurred when the soil temperature was maintained at 75° F. Higher temperatures were deleterious and at 95° F. less root growth occurred than with any other temperature within the range of 45–95° F.

Lowering of Sea-Level in Glacial Times

THE question of Quaternary sea-levels is an important one, especially in connexion with geomorphology and the migrations of plants, animals and man. Unfortunately, estimates of the lowering of the ocean surface due to the locking-up of water in the Pleistocene ice-sheets differ very widely. Antevs (1928) arrived at limits of 290–305 ft. for the fall in level due to the last glaciation, while Ramsay (posthumous publication in 1930) suggested limits of 183–275 metres for the lowering due to the maximum glaciation. The difference is out of all proportion to the difference between the volumes of ice involved in these two phases of glaciation. A. Farrington, in the *Proc. Roy. Irish Acad.*, **50**, 237 (1945), approaches the problem from a new direction. It is assumed that after the withdrawal of the last European ice-sheet the movements of land and sea were upwards in the main. In these circumstances the only evidence of the return of water to the sea is to be found in natural records of increasing depth. Brögger's study of the late-glacial deposits of the Oslo Fjord indicates that when the ice stood at the outer Ra, the older Yoldia clay was being deposited in water 10–30 m. deep. The younger Yoldia clay contains a fauna pointing to a depth of 40–60 m., while the later Arca clay has characters appropriate to deposition at 80–100 m. This evidence suggests that 70 m. is a conservative estimate for the rise of sea-level during the interval considered. It is further known that during the later period of the Ancyclus Lake the bed of the North Sea was dry land down to 50 m. below the present sea-level. A gap, including the Yoldia Sea period, intervenes between the two rises of more than 70 and 50 m., so that the total rise is at least 120 m., or 400 ft., since the beginning of the ice stand at the outer Ra. Remembering that the bulk of the European ice-sheet had already greatly wasted by the time it had retreated to the outer Ra, it follows, either that the North American ice-sheets melted later, which cannot be lightly assumed, or that the 400 ft. of recorded rise is only a part of the total rise. It is concluded that Antev's estimates of the change of sea-level and of the volume of the ice-masses are much too small.

Earthquakes in New Zealand during 1942–43

DURING 1942, 262 earthquakes and earth tremors had their epicentres in New Zealand (*Dominion Obs. Bull.* No. S-69. By R. C. Hayes, Wellington, N.Z. 1944). An epicentral map concerning these shows that by far the majority of the shocks occurred north of lat. 42·5° S., and very few occurred north of Auckland. According to Hayes, the most notable feature of the map is the concentration of activity in the Wairarapa district, due to the large number of subsidiary shocks following the outbreak of activity on June 24, 1942. Two other notable features during the year were: (1) the shock of June 27 with epicentre near White Island and focal depth 230 miles; this is the deepest origin so far recorded in the New Zealand region; (2) the shock of October 31 in the south-east Tasman Sea, where seismic activity very rarely occurs. During 1943, 213 earthquakes and earth tremors had their epicentres in New Zealand (*Dominion Obs. Bull.* No. S-71. By R. C. Hayes, Wellington, N.Z. 1944). The epicentral map in this case shows the same area as in 1942 covered with epicentres, except that during this year the shock area extended a little farther south, to lat. 43° S. Additionally there was an unusual amount of activity in the south-western portion of South Island, where two shocks reached minor destructive intensity (M.M.7). It was again noted by Hayes that there was a marked concentration of activity in the Wairarapa region, most of the shocks being of slight intensity.

Moving-Coil Instruments

THE design of moving-coil instruments includes a consideration of such factors as damping and speed of response, in addition to torque, resistance, etc. A paper by G. F. Tagg (*J. Inst. Elect. Eng.*, **92**, Pt. 2, No. 27, June 1945) presents the information necessary to understand the performance of a moving-coil instrument under various conditions in as complete a form as possible, and in such a form that it can readily be used. In the ordinary forms of instruments such as ammeters and voltmeters, the time/deflexion characteristics are of importance in determining the damping and the time of response, but have no effect on the steady reading of the instrument. In special types of instrument, such as the ballistic galvanometer and the flux meter, the time/deflexion characteristics are of importance in determining the reading given by the instrument.

'Cosmic Static'

THIS is the name given by Grote Reber (*Astrophys. J.*, **100**, 279; 1944) to naturally occurring short radio waves which reach the earth continuously at an intensity which is found to depend markedly on the direction of arrival. The radiation is apparently closely confined to the plane of the Milky Way. Measurements are made in the range 156–164 Mc./sec. (1·87 metres) with an $f/0{\cdot}6$ sheet-metal mirror 30 ft. in diameter mounted so as to swing in the meridian on a horizontal east-west axis. Electromagnetic radiation collected during the earth's rotation from a declination band determined by the elevation of the mirror is focused by it on to an antenna system which converts the waves into alternating current. This is then amplified and rectified and the resulting D.C. voltage drives a pen, which records on a moving tape the intensity of 'cosmic static' against right ascension for a given declination. A glance at specimen records shows that a marked maximum appears on the trace each time the mirror traverses the plane of the galaxy. The radiation becomes unmeasurably small at galactic latitudes above about 30°. There is also a strong dependence on galactic longitude: a main region of disturbance coincides with the direction of the galactic centre in Sagittarius, there are secondary maxima in Cygnus, Cassiopeia, Canis Major and Puppis, and a minimum occurs in Perseus. Though the absolute intensity is small (10^{-21} watts per megacycle band falling on a square centimetre from a square degree in Sagittarius), the effect is undoubted. Reber points out that the intensity from any direction seems to be roughly proportional to the amount of cosmic material in that direction, but ventures no suggestion as to the mode of production of this extraordinary radiation.

GROWTH INHIBITION IN PEA SEEDLINGS

By E. DOROTHY BRAIN

THE inhibition of the growth of lateral buds by the application of auxins in high concentrations to the apical surface of cut stems is well known, and it is often associated with marked swelling of the cut stems. Borgström[1] explains both the inhibition and the swelling as being due to increased supplies of auxin set free in a transverse flow from the phloem, induced by the decapitation of the main stem. He considers that the swelling is a secondary effect of the increased auxin supply and not otherwise related to the inhibition of the buds. In the experiments which are described below observations have been made on seedlings of *Pisum sativum* after treatment with *H* 11 extract of urine, three fractions of *H* 11 and some pure substances. The effect of the various applications on the growth of the cut epicotyls both in height and width and on the development and growth of lateral buds was examined. The plants were grown in pots of soil in the light until three or four internodes high, and then placed in the dark for twenty-four hours before experimenting and for forty-eight hours after treatment, being kept throughout the experiment under glass covers in a moist atmosphere. The inhibiting effect was calculated as the percentage difference between the averages for the total length of the side shoots in treated and control plants.

H 11 extract is an alcoholic extract of urine prepared by the Hosa Research Laboratories and used for treatment of tumour growth. The concentration of paste used for these experiments was equivalent to 3·5 c.c. *H* 11 extract in 6 gm. of pure lanoline. Tests were made with various dilutions of this. Treatment with concentrated paste when epicotyls were decapitated just below the terminal bud caused increased growth of the cut stems and marked swelling at the top of the stems. In plants decapitated at the node below which growth has ceased, treatment caused no increase in the height of cut stems nor did any swelling occur, but lateral buds were inhibited rather more than in the plants which had only the apical part removed.

Three fractions of *H* 11 extract were prepared by the Hosa Laboratories: (1) 80 *K* was prepared from the filtrate after the precipitation of neutral *H* 11 with copper sulphate; (2) 80 *L* was prepared from the soluble fraction after extracting the precipitate with dilute hydrochloric acid; (3) 80 *M* was prepared by dissolving the tarry substance which remained in 4 *N* sodium hydroxide. Lanoline paste was made with each fraction using 5 c.c. in 3·5 c.c. paraffin mixed with 2 gm. of lanoline. When applied to cut epicotyls 80 *K* and 80 *M* resulted in inhibition to side shoots, but 80 *L* had no inhibitory effect. 80 *L* and 80 *M* both caused greater swelling of the cut stem than 80 *K*. It appears as if 80 *K* contained an inhibitory substance which did not cause stems to swell as the other fractions did. Thompson *et al.*[2] found that 80 *M* was stimulatory to tumour growth.

As it was known that *H* 11 extract contained β-indole acetic acid and its sodium salt[3] a comparison was made between the effects of different concentrations of pure β-indole acetic acid and *H* 11, and it was found that a paste containing approximately 6,250 units β-indole acetic acid caused equivalent inhibition to the concentrated *H* 11 paste but less swelling of the stems. Series of experiments, in which paste made with a solution of β-indole acetic acid neutralized with sodium hydroxide was used, showed more swelling in the stems treated with the sodium salt than with the acid. The presence of the sodium salt in *H* 11 extract would therefore account for the marked swelling noted in the cut stems. Avery[4] has recorded that the potassium salt of β-indole acetic acid is twice as active as the acid in the *Avena* test.

Analysis of *H* 11 extract[5] having indicated the presence of a member of the quinone series, it was considered useful to test the effect of similar substances on cut stems. The following solutions were therefore used: (1) a saturated solution of anthraquinone in distilled water; (2) anthraquinone 2.6 di-sulphonic acid refined sodium salt, 0·1 per cent in distilled water; (3) 1.5 di-hydroxy anthraquinone, 0·1 per cent in distilled water. Results of these experiments showed a slight increase in the height of cut stems and inhibition of the growth of side shoots after treatment with anthraquinone and anthraquinone 2.6 di-sulphonic acid refined sodium salt. 1.5 dihydroxy anthraquinone caused less increase in the height of the cut stems and increased growth of side shoots. No swelling of the stems occurred.

Pisum sativum epicotyls

Applications to cut stems	Percentage inhibition of lateral shoots	Percentage increase in width of cut stems
H 11 extract	70·2	150·0
Fractions of *H* 11		
80 *K*	42·86	50·0
80 *L*	—	100·0
80 *M*	41·67	100·0
β-indole acetic acid, 6,250 units per gram lanoline	69·6	76·8
Anthraquinone saturated solution	73·4	—
Anthraquinone 2.6 di-sulphonic acid refined sodium salt 0·1 per cent	54·4	—
1.5 di-hydroxy anthraquinone 0·1 per cent	—	—

A comparison of the amount of inhibition and swelling caused by these different applications is given in the accompanying table. It is evident from these results that substances which cause inhibition may not cause swelling in the stem and that auxin application may inhibit without causing swelling if the actively growing internodes of the stem are removed.

Snow[6] states that the inhibitive influence travelling up the lateral shoot is a hormone other than auxin and finds evidence in his experiments that another substance is active in inhibiting lateral buds in pea seedlings. No previous record has been found of inhibition by substances other than auxin when applied apically to the cut stem, and it is hoped to carry out more experiments to test the inhibition of other substances along these lines.

I am indebted to Mr. J. H. Thompson, director of research of Hosa Research Laboratories, for providing the *H* 11 extracts and other substances.

CELL PROLIFERATION, CARBOHYDRATE BREAKDOWN, AND HYDRATION OF ENZYME PROTEIN

By Dr. A. LASNITZKI
Department of Physiology, University of Birmingham

THE interesting result that the rate of anærobic glycolysis of embryonic and post-embryonic tissue, from a warm-blooded animal, decreases gradually in successive stages of development[1,2] has demonstrated a close relationship between enzymatic breakdown of carbohydrates, particularly that of glucose, and the proliferation of tissue cells, having regard to the fact that, in general, the rate of this proliferation likewise diminishes as development progresses[3]. The significance of this parallelism has further been emphasized by the result that, in normal tissues, the rate of anærobic glycolysis corresponds approximately to the rate of carbohydrate oxidation under ærobic conditions[4].

The most appropriate interpretation of the relation appears to be that the energy required for cell proliferation originates, directly or indirectly, in carbohydrate breakdown; in particular, this view indicates that the relation must hold for any type of growing tissue, including tumour tissue, the latter possessing a considerable ability to metabolize glucose, although this is, even under ærobic conditions, largely confined to anoxidative glucose splitting[1,2,4]. A distinction must be made, however, between the *supply* of energy by a process of this kind and the final *utilization* of that energy for the purpose of growth, and the possibility of a disconformity between these two factors must be considered in estimating the result that, in the case of tumours, rate of cell proliferation and intensity of glycolysis have not shown throughout the same clear relation obtained with tissues growing normally[5]. On the other hand, in certain tissues of the adult organism (for example, nervous tissue), in which cell proliferation has come to an end, although a relatively high carbohydrate metabolism persists[1,4], it is an obvious assumption that the liberated energy will be utilized for the maintenance of specialized functions.

Another fact of relevant interest is provided by the observation, frequently noted, that the water content of the entire animal body as well as of individual tissues gradually decreases in the course of embryonic and post-embryonic development, so that rapidly growing tissues, that is, tissues with intense cell proliferation, as a rule contain more water than corresponding tissues growing at a slower rate[6]. A very similar relation was found for tumour tissue[7]. In all probability, the increase in tissue water is due in great part to a rise in water content of the cellular constituents, and this rise is likely to be associated with an increased hydration of cell proteins. The most important kinds of proteins, in this connexion, appear to be those which constitute the protein components of enzymes, and, in particular, of such enzymes as are involved to a varying extent in the breakdown of carbohydrates.

These considerations suggest, therefore, that the intensity of carbohydrate breakdown in a growing tissue, and consequently the rate of cell proliferation, depends largely on the degree of hydration of corresponding enzyme proteins, so that, within limits, an increase in hydration stimulates and a decrease inhibits that enzymatic activity[8]. The suggestion attempts to elucidate the biological significance of the increased water content of rapidly growing tissues by relating it, through the concept of protein hydration, to the metabolic process which serves as the source of energy for cell proliferation; and the order of causation thus supposed can be represented as follows:

1		2		3
Degree of hydration of enzyme proteins involved in carbohydrate breakdown	→	Intensity of carbohydrate breakdown	→	Rate of cell proliferation.

Some experimental evidence regarding the validity of relation 1 → 2 may be obtained from the results of studies on the action of ions upon glycolysis and related processes. Thus it was found[9] that the splitting of 'lactacidogen' (probably a hexosephosphate) by frog muscle could be modified under the influence of various anions in a manner which, on the whole, corresponded to their position in the Hofmeister series, anions with hydrating effects upon proteins (and hydrophilic colloids in general) causing an acceleration, and those with dehydrating effects an inhibition, or even reversion, of the process. As to warm-blooded animals, a number of investigations[10] have shown the pronounced inhibitory effect of fluoride upon the glycolytic activity of normal tissues and tumours, an effect which agrees with the strongly dehydrating power of that anion; while other studies[11,12], likewise performed with both normal and tumour tissue, have shown that glycolysis, as well as carbohydrate oxidation, could be markedly stimulated by potassium, a cation which favours hydration.

TWO NEW ANTIBIOTICS

IN a note in *Nature* of November 18, 1944, p. 631, attention was directed to the need for an antiseptic or antibiotic which would effectively control infections with Gram-negative micro-organisms, many of which are not susceptible to penicillin. Among these are the typhoid-dysentery group of organisms, *Brucella*, *Hæmophilus* and those common invaders of wounds, *Proteus vulgaris* and *Pseudomonas pyocyaneus*. The tubercle bacillus is also resistant to penicillin. A reference has now appeared (*Brit. Med. J.*, 706, May 19, 1945) to two new antibiotics derived from soil Actinomycetes which do act upon various Gram-negative organisms and also seem to inhibit the development of tuberculosis in guinea pigs. They have been isolated by S. A. Waksman and his colleagues (*Proc. Mayo Clin.*, 19, 537; 1944; and *Proc. Soc. Expt. Biol., N.Y.*, 55, 66; 1944) and are called 'streptomycin' and 'streptothricin'. Streptomycin seems to be the more valuable of the two. It is obtained from *Actinomyces griseus* and, like streptothricin, is very stable and resists moderate heat, storage and the action of most other organisms, in marked contrast to penicillin. It appears to be an organic base, soluble in water, but not in ether and chloroform. It inhibits *in vitro* the growth of human strains of the tubercle bacillus, the Gram-positive *B. subtilis* and *Staphylococcus aureus*, and the Gram-negative *Bact. coli, Brucella abortus, Bact. aerogenes* and various organisms of the *Salmonella* and dysentery groups. It has, unlike penicillin, a moderate inhibitory action upon the growth of *Proteus, Salmonella aertrycke* and *Pseudomonas pyocyanea.* Its toxicity to animals is fairly low. The antibacterial action of streptothricin is similar, but less powerful; and it acts upon fewer organisms.

No clinical trials have yet been reported with these substances, but tests done on mice show that streptomycin very effectively protects mice against mixed infections with *Proteus vulgaris* and an anaerobic streptococcus, both obtained from a human infection. Good results have followed the treatment with streptomycin and streptothricin of mice and chick embryos infected with various *Salmonella* species and with *Brucella abortus*. Heilman (*Proc. Mayo Clin.*, 19, 553; 1944) has reported that *Pasteurella tularensis*, the cause of tularæmia, which is not affected by sulphonamides or penicillin, is three times as sensitive as *Bact. coli* to streptomycin, which prevents infection of mice with *P. tularensis*. Feldman and Hinshaw (*Proc. Mayo Clin.*, 19, 593; 1944) have shown that, in guinea pigs inoculated with virulent tubercle bacilli and treated for sixty days with streptomycin, tuberculosis was scarcely detectable microscopically, although viable bacilli were still present, while the control animals not so treated showed widespread tuberculosis. The antibacterial action of streptomycin is, these authors think, comparable to that of promin, which they also studied.

It is clear that streptomycin and streptothricin urgently require further clinical study. An important obstacle to their clinical trial on a sufficiently extensive scale may well be the difficulty of producing them in sufficient quantity, and it is to be hoped that it will be possible to overcome this. There is considerable evidence that, although the remarkable properties of penicillin justify all the effort that is being expended upon it, that effort must not distract attention from the other antibacterial substances which are being constantly isolated from an increasing variety of living organisms. Among these the soil bacteria are important. The properties of gramicidin and gramicidin S, obtained from soil bacteria, were noted recently in *Nature* (246, Feb. 24, 1945). Another heat-stable substance which is chemically similar to, but apparently not identical with, the gramicidin isolated by Hotchkiss and Dubos in America (see *J. Exp. Med.*, 73, 629; 1941 and other papers) has been isolated by J. C. Hoogerheide (*J. Bact.*, 40, 415; 1940, and *J. Franklin Inst.*, 229, 677; 1940) from soil bacteria. It prevents the formation of the capsule by Friedlander's bacterium, types *A* and *B*. Its chemical, therapeutic and other properties are summarized by E. McDonald (*J. Franklin Inst.*, 229, 805; 1940). Dr. V. W. Murray Wright reported that the material originally isolated by Hoogerheide from the bacteria was "very valuable and safe" for the treatment of *external* lesions in human patients. Dr. Wright (*J. Franklin Inst.*, 233, 188; 1942) also reports on a series of ninety human cases infected with Gram-positive organisms and treated with what is apparently the same substance (designated *H* 1). The organisms rapidly disappeared and healing was stimulated. G. LAPAGE.

UNITED STATES ANTARCTIC DISCOVERIES

THE work of the United States Antarctic Service Expedition of 1939–41 has been overshadowed by war and was little known in Great Britain. The volume now published (Reports on the Scientific Results. New York: *Proc. Amer. Phil. Soc.*, 89, No. 1, 1945) gives full accounts of all aspects of the expedition's work in a long series of papers, many of which are well illustrated but none of which is well supplied with maps.

This was Admiral R. E. Byrd's third expedition, but the first official United States expedition to the Antarctic for a hundred years. It was well equipped and carried a large scientific staff to its two bases, the east base in Marguerite Bay, Graham Land, wrongly called the Palmer Peninsula, and the west base at the Bay of Whales on the Ross Barrier. The first was new territory for the Americans; the second was in an area where much American work had already been done, but it seems, at the least, ungracious to reduce Scott's King Edward VII Land to a mere peninsula of Marie Byrd Land.

Discoveries made by plane and sledge journeys were noteworthy, and geological work was a feature of all land travel. Several of the most important papers in this symposium are by Lieut.-Com. R. B. Black, Com. F. Ronne, Major P. A. Siple, Major F. A. Wade, L. A. Warner, C. F. Passel, P. H. Knowles and Prof. D. Stewart. A sledge journey along King George VI Sound and a flight west of Alexander I Island carried the map west of the discoveries of the Rymill expedition. Alexander I Land is certainly an island, and west of it lies the much smaller Charcot Island. West of King George VI Sound the coast-line seems to run mainly east and west to high land in about long. 95°–100° W. South Graham Land is a plateau of some 4,000–5,000 ft. uncut by straits, and facing the Weddell Sea is the lofty edge of the George Black Range in about long. 60° W. from about lat. 72° S. to 77° S.

On the other side of Antarctica, the Edsel Ford ranges of Marie Byrd Land were well explored, and the coast-line, Hobbs Coast, continued east of Cape Rupert. Several flights across the Ross Barrier were also made. Evidence was found of several small islands under the Barrier, smaller than Roosevelt Island. There was little evidence of the Barrier having calved in recent years. It is suggested that the Bay of Whales is the meeting-place of two shelf-ice systems, on the western side from the south and on the eastern from the south-east. These systems thus cause crumbling of bay-ice in that area. No suggestion was noted of sea-level connexion between the Ross and Weddell Seas.

Some light was thrown on the problem of the relationship of the Andean structure of Graham Land with the predominant plateau structure of the greater part of Antarctica. The Rockefeller Mountains of King Edward Land and the Edsel Ford ranges of Marie Byrd Land are both a series of north-west trending folds of metamorphics and acid intrusives: "No true relationship is indicated between this unit and any of the previously described Antarctic localities". But on the whole the affinities seem to be with the Andean structure. The new land examined in the south of Graham Land is definitely Andean in structure, though the Weddell Sea coast has a definite block fault topography with much granite and slate.

Many other valuable researches are discussed in this volume. R. N. RUDMOSE BROWN.

FORTHCOMING EVENTS

Monday, October 1

BRITISH MUSEUM (NATURAL HISTORY), South Kensington, London, S.W.7, at 2.30 p.m.—Dr. J. Ramsbottom, O.B.E.: "Edible Fungi". Also on Mondays and Fridays until October 26.

ROYAL INSTITUTION (Albemarle Street, London, W.1), at 5 p.m.—Lord Rayleigh, Sir Robert Robertson, Sir Richard Paget, Mr. R. S. Whipple, Prof. W. V. Mayneord and Sir Henry Dale: Life and Work of Major C. E. S. Phillips

SOCIETY OF ENGINEERS (at the Geological Society, Burlington House, London, W.1), at 5 p.m.—B. A. P. Winton Lewis: "The Engineer and the Housing Problem".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 7.15 p.m.—Dr. E. S. Hedges: "New Developments in Tin and Tin Alloy Coatings".

Wednesday, October 3

INSTITUTE OF WELDING (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 6 p.m.—Mr. W. K. B. Marshall: "The Fabrication of Aircraft Fuel Tanks in Aluminium Alloy containing 3% Magnesium" (Sir William J. Larke Medal Prize Paper).

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Mr. Eric C. Wood: "The Theory of certain Analytical Procedures, with special reference to Microbiological Assays".

Thursday, October 4

ROYAL COLLEGE OF SURGEONS OF ENGLAND (Lincoln's Inn Fields, London, W.C.2), at 5 p.m.—Dr. Leslie Foulds: "Observation and Theory in Cancer Research" (Imperial Cancer Research Fund Lecture).

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. U. R. Evans: "Recent Work on Corrosion and Oxidation Reactions".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Dr. P. Dunsheath: Inaugural Address as President.

Friday, October 5

BRITISH RHEOLOGISTS' CLUB (at the Engineers' Club, Manchester), at 11 a.m.—Business Meeting; at 2 p.m. (joint meeting with the MANCHESTER SECTION OF THE OIL AND COLOUR CHEMISTS' ASSOCIATION)—Discussion on "General Rheological Properties of Suspensions" (to be introduced by Mr. J. Pryce Jones and Mr. W. F. Carey)

ASSOCIATION OF APPLIED BIOLOGISTS (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 11 a.m. and 2.15 p.m.—Symposium on Some Agricultural Uses of D.D.T.

PHYSICAL SOCIETY (at the Physics Department, Imperial College, London, S.W.7), at 5 p.m.—Dr. D. H. Smith: "A Method for obtaining small Mechanical Vibrations of known Amplitude"; Dr. S. R. Pelc: "The Photographic Action of X-Rays"; Rev. G. D. Yarnold: "The Hysteresis of the Angle of Contact of Mercury".

SOCIETY OF CHEMICAL INDUSTRY, PLASTICS GROUP AND GLASGOW SECTION (at the Royal Technical College, Glasgow), at 7.15 p.m.—Prof. H. W. Melville: "Structure and Synthesis of Vinyl Plastics".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

TWO ASSISTANT LECTURERS IN APPLIED MATHEMATICS in the University of Liverpool—The Registrar (Oct. 1)

PRINCIPAL at a Farm Institute for Training ex-Service men, to be opened in Norfolk—Executive Officer, Norfolk War Agricultural Executive Committee, Sprowston, Norwich (Oct. 3).

DISTRICT OFFICER to the Berkshire War Agricultural Executive Committee—The Secretary, 1 Abbot's Walk, Reading (Oct. 6).

LECTURER IN ORGANIC CHEMISTRY at the Mid-Essex Technical College, Market Road, Chelmsford—Chief Education Officer, County Offices, Chelmsford (Oct. 6).

LECTURER with special responsibility for AERONAUTICAL ENGINEERING at the Technical College, Coventry—Director of Education, Coventry Local Education Authority (Oct. 8).

GRADUATE TEACHER OF ELECTRICAL ENGINEERING and allied subjects at the School of Engineering and Navigation, High Street, Poplar, London, E.14—The Education Officer (T.1), County Hall, London, S.E.1, on application form T.1/40, for which a stamped addressed envelope should be sent (Oct. 8).

LECTURER IN GEOGRAPHY at the London School of Economics and Political Science, Houghton Street, London, W.C.2—The Secretary (Oct. 8).

GRADUATE ASSISTANT to teach ENGINEERING SUBJECTS at the Stockton-on-Tees Technical School—The Director of Education, Shire Hall, Durham (Oct. 10).

One CHIEF CHEMIST (Ref. F.4816 XA), four ASSISTANT CHEMISTS (Ref. F.4817.XA), and one ASSISTANT MECHANICAL ENGINEER (Ref. C.2797.XA), in a South American spinning rayon plant—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting appropriate Ref. No. (Oct. 12).

DIRECTOR-GENERAL OF THE BRITISH PRODUCTION ENGINEERING RESEARCH ASSOCIATION—The Association, Box A.1188, *The Times*, London, E.C.4 (Oct. 19)

DEVELOPMENT ENGINEERS (copper and copper alloys), one ELECTRICAL (D.1388.XA) and one MECHANICAL (C. 2736.XA)—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting appropriate Ref. No. (Oct. 19).

DISTRICT ENGINEER (civil) for the Sudan Government—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting E.1954.A (Oct. 20).

DIRECTOR OF RESEARCH, Institution of Automobile Engineers—The Chairman of the Institution, Research Department, Great West Road, Brentford, Middlesex, marked "Director of Research" (Oct. 20).

Two DISTRICT LOCOMOTIVE SUPERINTENDENTS for the Sudan Government—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting C.2798A (Oct. 20).

PHYSIOLOGIST at the Laboratory of the Marine Biological Association of the United Kingdom, Citadel Hill, Plymouth—The Secretary (Oct. 31).

CURATOR OF VERULAMIUM MUSEUM, St. Albans—The Town Clerk, St. Albans, endorsed "Curator" (Oct. 31).

SUB-LIBRARIAN in the University Library, St. Andrews—The Librarian (Nov. 1).

DEPUTY CITY ANALYST, City and County of Bristol—The Medical Officer of Health and Professor of Preventive Medicine, Department of Public Health, Kenwith Lodge, Westbury Park, Bristol 6, endorsed "Deputy City Analyst" (Nov. 3).

JACKSON CHAIR OF ENGINEERING in the University of Aberdeen—The Secretary (Nov. 15).

RUTHERFORD MEMORIAL RESEARCH FELLOWSHIP (physics, chemistry and/or mathematics) at Canterbury University College, Christchurch, New Zealand—The Secretary, Universities Bureau of the British Empire, care of University College, Gower Street, London, W.C.1 (applications to reach New Zealand by January 31, 1946).

DEMONSTRATOR IN PHYSICS at Guy's Hospital Medical School, London, S.E.1—The Dean of the School.

CHIEF DEVELOPMENT ENGINEER to the Research and Development Department, United Steel Companies, Ltd.—The Secretary, 17 Westbourne Road, Sheffield, 10.

CHAIR OF MINING AND METALLURGY, CHAIR OF ELECTRICAL ENGINEERING, and CHAIR OF MECHANICAL ENGINEERING, University of Adelaide—The Secretary, Universities Bureau of the British Empire, care of University College, Gower Street, London, W.C.1

HEAD OF THE ENGINEERING DEPARTMENT, Municipal College, Bournemouth—The Director of Education, Town Hall, Bournemouth.

PRINCIPAL OF THE LOWESTOFT TECHNICAL INSTITUTE—The Chief Education Officer, County Education Department, County Hall, Ipswich.

LECTURER IN ELECTRICAL ENGINEERING, and LECTURER IN MECHANICAL ENGINEERING, in the Nottingham and District Technical College—The Acting Clerk to the Governors, Education Office, South Parade, Nottingham.

ASSISTANT (graduate in zoology or physiology) FOR CANCER CHEMOTHERAPY INVESTIGATIONS—Hosa Research Laboratories, Sunbury-on-Thames.

TECHNICAL ASSISTANT IN THE GEOLOGY DEPARTMENT, University of Birmingham—Prof. L. J. Wills.

ASSISTANT LECTURER AND DEMONSTRATOR IN PHYSICS at the Royal Holloway College, Englefield Green, Surrey—The Principal.

LECTURER IN PHYSICS at the Stockport College for Further Education—The Deputy Director of Education, Education Offices, Town Hall, Stockport.

GRADUATE LECTURER IN MECHANICAL ENGINEERING SUBJECTS at the Kingston Technical College—The Principal.

DEMONSTRATORS IN PHYSICS, BIOLOGY and CHEMISTRY (one each), and a TECHNICIAN, at St. Bartholomew's Hospital—The Vice-Dean of the Hospital, at Queens' College, Cambridge.

AN INTERNATIONAL SCIENCE CO-OPERATION SERVICE

WHILE scientific workers may well find it scarcely less difficult than their fellow citizens to grasp as yet the full implications of the new force resulting from scientific discovery which we have seen in action in the atomic bomb, they will unhesitatingly endorse Mr. Attlee's view that a re-evaluation of the whole situation, especially in the sphere of international relations, is required. This is particularly true in respect of the exchange and dissemination of information and of the organization of defence, to both of which questions scientific men in Britain have been giving close attention during recent months. Nothing can stop the progress of research and experiment in every country; but although research will no doubt proceed in many places, the immense plants necessary to transform theory into action cannot well be constructed in countries not possessing the necessary resources. Our organization of scientific research and development, the whole system of the organization and co-ordination of the nation's resources for defence purposes, which Lord Hankey reviewed under a somewhat misleading title in his recent book, "Government Control in War", must be reconsidered in the light of this new situation.

This no doubt will be one of the prime tasks of the new Atomic Energy Advisory Committee which, as announced on August 21, the Government has set up, under the chairmanship of Sir John Anderson, to assist in dealing with the many far-reaching questions raised by this new discovery, in connexion with its international treatment and its further development in Britain, for both industrial and military purposes. This Committee is not intended to deal with policy, which no doubt will be fully considered not only by the Government itself, but also, if not by the Executive Committee of the Preparatory Commission of the United Nations, then by the Security Council, as Mr. Bevin's statement on August 16 indicated. The exchange of scientific information and of scientific co-operation is thus again to the fore, and the ideas put forward last year by Dr. Joseph Needham for the organization of an international science co-operation service acquire fresh significance.

The choice is in fact not between secrecy and disclosure, but between co-operative and competitive knowledge. It might be held a sensible precaution for the United States to hold her secret until agreement has been reached upon the form of the new world control and until the appropriate machinery has been built into the United Nations organization; but that control must be based on the pooling of knowledge, upon the recognition that, as the Archbishop of Canterbury pointed out, it is the duty of men of science to explore and to find out with all the abilities they have, and to extend the knowledge of this universe. That duty can only be discharged while there is the fullest communication between scientific men of all countries; and although there may be room for much discussion as to the form the control now required should take, it must be recognized from the start that full freedom of scientific intercourse is a first condition. Without that there can be neither effective control in seeing that this discovery is not turned to destructive ends, nor the best use made of it for peaceful purposes.

One of the first steps to be taken is thus, as Sir Henry Dale suggested in his letter in *The Times*, the encouragement of the fullest possible publication of the results of scientific research and of the full freedom of science for which he pleaded. It is not merely that progress in science really depends on such freedom of intercourse; from the point of view of world order and security, such freedom would also be a useful means of indicating danger points. Restrictions or refusal to participate would not be easily concealed from the scientific community; and once the existence of such an attitude was established, the world organization should be able to deal appropriately with the situation before it became unmanageable. Furthermore, the historical survey of the scientific discoveries which led to the idea of the atomic bomb contained in the Statement issued by the Department of Scientific and Industrial Research on August 12, 1945, well illustrates the truth that scientific effort proceeds on parallel lines in different countries, and effective contact and intercourse between the scientific men of the United Nations should in itself be a safeguard against any sudden advance elsewhere, the application of which might endanger the peace of the world.

Dr. J. Needham, writing from Chungking, has now prepared for private circulation a memorandum on the place of science and international scientific co-operation in post-war world organization, in which he reviews the reception of his earlier proposals and discusses their incorporation in a United Nations organization such as that which was recently considered by the Conference of Allied Ministers of Education. Prof. A. V. Hill's address on "Scientific Co-operation within the British Commonwealth" before the Royal Empire Society on January 31 (see *Nature*, 155, 373; 1945) elaborated proposals for a more limited field, but with their bearing on international scientific co-operation clearly in mind. The recent visit of British and other men of science to Moscow for the anniversary celebrations of the U.S.S.R. Academy of Sciences has provided further evidence of the concern and desire of scientific men everywhere for fuller and free international contacts.

The dependence of all modern world civilization on applied science must find its expression in the sphere of international relations, and Dr. Needham notes that this desire is more strongly expressed the further one goes away from the great scientific and industrial centres of Europe and the United States. One reason for this is, as he shows in his memorandum, that the picture of world science looks very different when seen from Rumania, Peru, Siam or China, where it may be very difficult for one man of science to establish contact with another in a different part of the world. It is particularly the scientific workers and technologists in the far larger regions of the world outside Western Europe and North America who need the help of an international science co-operation service.

Dr. Needham points out that such a service should be directed and limited to doing those things that are not being done, and cannot be done in other ways. It must also avoid the danger of a paper organization incapable of functioning effectively, and undue bureaucracy through failure to select the right staff. Adequate office management would avoid the first danger, and full participation by scientific men themselves the second. He should also have added, however, that no new organization should be established where the development or modification of existing organizations would serve.

Since these proposals were advanced last year, draft proposals for an educational and cultural organization of the United Nations have been published (see *Nature*, Sept. 1, p. 263). The purposes of this organization are "(1) To develop and maintain mutual understanding and appreciation of the life and culture, the arts, the humanities and the sciences of the peoples of the world as a basis for effective international organization and world peace". The principal functions of the organization would be to assist the free flow of ideas and information among the peoples of the world through schools, universities and other educational and research institutions, libraries, publications and the Press, the radio and motion picture, international conferences and the exchange of students, teachers and all other representatives of educational and cultural life, with special attention to the exchange of information on major educational and cultural developments, including advances in scientific knowledge. They also include fostering the growth of educational and cultural programmes which give support to international peace and security, and conducting and encouraging research and studies on educational and cultural problems related to the maintenance of peace and the advancement of human welfare.

The activities thus contemplated cover most of the twenty-four specifically listed in the draft cited in Dr. Needham's memorandum, and scientific activities are more implicitly covered, though the restoration of physical facilities including laboratories and equipment and scientific libraries in the liberated and ravaged countries is not mentioned. Since, however, the word 'culture' does not possess in all countries the wide connotation it has in the United States, Dr. Needham is on firm ground in insisting that the word 'science' should appear in the actual title of the organization, and in suggesting that it should be termed the United Nations Educational, Scientific and Cultural Organization. Moreover, the Organization should cover both pure and applied science, which cannot be separated.

Dr. Needham sets forth thirteen aims for the scientific division of the new Organization which overlap with those already mentioned but cover the field of science more adequately, and have much in common with the agenda Prof. A. V. Hill suggested for the Empire Scientific Conference. First, there is the general aim of promoting international scientific co-operation in all its aspects. Next, he puts organization of the better exchange of scientific information and research services between scientific men and their organizations in the different countries. Here Dr. Needham refers to the enormous task of seeing that the information actually published by government scientific organizations reaches those who need it, both far and near. In this connexion his work in China has clearly impressed upon him the need for increasing the availability of scientific periodicals, both current issues and the back runs of the more important periodicals. Besides the question of reproduction which may be involved here, there is the exchange of reprints, and Dr. Needham suggests that a central stockpile might be of great value to scientific workers by facilitating distribution.

In elaborating this point, Dr. Needham ventures into a highly technical field; but it may well be argued that some such organization as he advocates would prove the best means of securing an objective study of the problems and encouraging, not the development of a number of new *ad hoc* organizations, but rather the expansion of existing organizations so that they could serve adequately the needs of to-day. He also suggests in the same connexion that much help could be given to scientific workers by arranging for the wider use of special apparatus only available at certain places, while a specific aim should be that of assisting the free flow of essential research apparatus, chemicals and equipment across national frontiers. This function would involve assisting a wide distribution of the catalogues of firms producing scientific equipment, and possibly some assistance in the matter of customs dues and procedures. Some of these points have already been emphasized by the Committee on Scientific Equipment of the Conference of Allied Ministers of Education. As one of three short-term aims, Dr. Needham mentions the elaboration of a plan for utilizing surplus war material and equipment suitable for use in research and its transfer to the more scientifically backward countries.

Another aim would be the maintenance of contact between government organizations concerned with science, pure and applied, when necessary, and advising government and diplomatic personnel on scientific matters. This applies to the smaller Powers particularly, for even if the practice of appointing scientific attachés in the embassies of the larger Powers becomes established, the smaller Powers may well lack the personnel to make such appointments. Again, the need is stressed for assisting the free flow of scientific books, periodicals, manuscripts for publication, translations, abstracts, etc., across national frontiers, and especially between world regions of widely different linguistic pattern. Here he has in mind both encouraging the publication of scientific results in the major scientific periodicals in the better-known languages, and also the rationalization of the present system of abstracting scientific publications. An International Science Co-operation Service should be able to do something to prevent the dissipation of scientific publication on purely nationalistic grounds. t might assist the effort which the British Commonwealth Science Committee contemplates in its report for a common abstracting service for the English-speaking nations, and develop this ultimately into a central abstracting organization issuing the abstracts in the three or four main world languages simultaneously.

Realization of such plans at present lies far ahead, but progress is scarcely possible except through an organization of the type Dr. Needham has in mind. Even within a single country, there is still much parochialism among scientific workers to be broken down before co-operative enterprises in such fields as abstracting can achieve full success. Probably Dr. Needham's next objective, assisting the free flow of scientific workers across national boundaries, is one where the organization he suggests might function with more immediate effect. Dr. Needham quotes Sir David Rivett, Dr. Coumoulos and Prof. J. B. S. Haldane to illustrate the importance of this objective, and refers also to such matters as the preparation of scientific expeditions in zoology and astronomy, and for the investigation of the natural products of interesting parts of the world where local effort would be unable to finance such projects. Dr. F. W. Went's proposal for the organization of temporary research groups in specific topics in fields such as genetics, cytology, physiology and morphology is a further example of how valuable such an international science co-operation service might prove.

Overlapping with this aim, Dr. Needham suggests the promotion of plans for international collaboration in research, and has in mind both close contact with the international scientific unions which, in such sciences as astronomy, geophysics, geodesy and radio physics, have been outstandingly successful in the past, and the establishment of similar bodies for other sciences, as well as encouraging the activities of such organizations as the International Committee on Zoological Nomenclature. He illustrates his point by showing how an international science co-operation service could help in rapidly supplying contacts needed in research and by rendering the dissemination of scientific information less haphazard. This aim would also cover the preparation and maintenance up to date of a register of scientific institutions of all kinds and of their staff members and specialities.

Again, the new organization would support all international activities of the various national academies of science, and assist the work of other international organizations, such as the United Nations Food and Agriculture Organization and Relief and Rehabilitation Administration, the International Labour Office, etc., in scientific questions. Such development would be greatly facilitated by the development of the expected science co-operation service of the British Commonwealth after the War and like bodies, the International Resources Office, or the International Development Authority called for at the Bretton Woods Conference. On the other hand, the organization suggested by Dr. Needham might be able to combine into one body some of the smaller international scientific bodies such as the United Nations Standard Co-ordinating Committee, the World Power Conference, the International Fisheries Board, and also provide central secretariat facilities for the international scientific unions and congresses.

From Dr. Needham's experience with the British Council Scientific Office in Chungking, and from the work of the United States Interdepartmental Committee of Cultural and Scientific Co-operation with the American Republics, he is able to supply concrete examples of the kind of work which the organization he suggests might do. Furthermore, while the work of the organization would chiefly be related to that of the Social and Economic Council of the United Nations, in one matter at least it would be related to that of the Security Council. Dr. Needham suggests that the organization should be concerned with the control of the activities of scientific workers in the ex-Axis countries so as to prevent the building up of war potential while permitting the renaissance of scientific thought which must have a place in the re-education of these peoples. With an international science co-operation service, it should be almost impossible for the significance of such developments as the Haber ammonia synthesis to be overlooked, and this factor has a vital bearing on the elaboration of any plans for the control of atomic energy.

As to further association of the organization with industrial activity, Dr. Needham is a little vague. He thinks that some help might be offered in the simplification of world patent law and that by means of such an organization the maximum goodwill could be focused on the development of the backward countries. Dealing with the probable cost and structure of the proposed organization, from the cost of the British scientific office in Washington and in China and the United States Cultural Division of the State Department (Far East Section), he suggests that the annual budget should be about three million dollars, providing for a liberal number of field offices. It is essential, however, that the scientific organization be not radically understaffed or starved of funds, and the headquarters' secretariat must be supported by a resident staff in the more backward countries, where the prestige of science is weak and the influence of local politicians with no understanding of science is strong. Not more than two or three of the scientific representatives in such a field office need be of outside nationality, and for some regions a field office could cover several national entities or domains.

Dr. Needham is not pessimistic as to the possibility of securing the right staff, and points to the fund of wisdom and experience which could be drawn upon by utilizing men in the five-year period after retiring age. The business of the scientific liaison officer, he emphasizes, is not necessarily to know the answer; but to know where the answer can most probably be obtained. He also emphasizes the need for assuring the officials of the organization of some kind of diplomatic status, with guaranteed facilities for transport and communication.

Dr. Needham has been at some pains in formulating his scheme to avoid the weaknesses in the International Institute of Intellectual Co-operation, but although it may be assumed that the principal place for science in the international scheme is the United Nations Educational and Cultural Organization, with the title modified as suggested, many scientific men will be working with other functional organizations, such as the Radio Communications Organization, the Civil Aviation Board, the Food and Agriculture Organization, the International Health Organization. Accordingly, it has been proposed that a scientific body might be introduced at a higher level than any one of the functional organizations; so Dr. Needham suggests that the United Nations should include, as a counterpart of the Economic Commission and the Social Commission, a Scientific Commission and a Scientific Secretariat. The Commission might consist of about a dozen eminent men of science of the older generation, and the secretariat of a score or so younger men of science, mostly on a short-term service basis. This Scientific Commission of the Economic and Social Council would provide an easy means of linking the work of all scientific men in the functional organizations; but Dr. Needham himself appears to lean rather to the idea of an Educational, Scientific and Cultural Organization, functioning on the lines already indicated, and worked out in detail by a world conference of science; such a conference has already been recommended by the National Academy of Sciences of the United States. Nevertheless, although most of Dr. Needham's suggestions are to be found in current discussions on problems of scientific relations, it may well be open to question whether the time is really ripe for such a world conference. So far as the British Commonwealth is concerned, these questions will largely be covered by the Empire Science Conference to be called next summer by the Royal Society, and the improvement of scientific co-operation and communications within the British Commonwealth is an essential factor in promoting any wider schemes.

What appears to be of the first importance at the present moment is to see that the full fruits of wartime experience are reaped, and that machinery for co-operation for war purposes, whether within or without the British Empire, which has proved its value, should not be thrown away. To develop and utilize fully existing organizations rather than to elaborate fresh organizations should be a guiding principle. It is true we may well hope for the establishment of an Indian Scientific Office with an Indian Scientific Liaison Service, and the position with regard to the Middle East Supply Centre may require careful watching if the valuable scientific work already initiated under it is not to be jettisoned. That in itself is a matter for international collaboration, and the Empire Science Conference is unlikely to disregard the work of the British Central Scientific Office in Washington, the Scientific Office of the British Council in China, or the experiment with scientific attachés which Australia has initiated. Furthermore, those considerations of imperial defence to which Prof. A. V. Hill referred in his address to the Royal Empire Society on January 31 have been powerfully reinforced by the advent of the atomic bomb; and policy in this matter cannot be worked out in isolation. Dr. Needham's proposals may appear premature in some respects, but between now and the meeting next summer of the Empire Scientific Conference there should be clear thinking among scientific workers of the Commonwealth as to the precise ways of improving means of communication and co-operation within and without the British Empire, and the extent and delimitation of any new organization to be established for such purposes. Such consideration must necessarily take account of the draft proposals for a United Nations Educational and Cultural Organization, and a decision reached as to how far such an organization can serve the needs of science, what modifications, if any, are required in title or in structure, and whether or not scientific organizations can usefully co-operate. Dr. Needham has at least challenged the constructive thinking which is essential in order to seize the opportunities of the post-war world.

PROTEINS, AMINO-ACIDS AND PEPTIDES

Proteins, Amino-Acids and Peptides as Ions and Dipolar Ions

By Edwin J. Cohn and John T. Edsall, with chapters by John G. Kirkwood, Hans Mueller, J. L. Oncley and George Scatchard. Pp. xviii+686. American Chemical Society Monograph Series. (New York: Reinhold Publishing Corporation, 1943.) 13.50 dollars.

THE misfortunes of war have rendered this impressive book, published in 1943, inaccessible in Britain until recent months. No shorter description is possible than to say it is worthy of those great men to whom it is dedicated, Bate Hardy, Loeb, Osborne and Sørensen.

The book is wholly devoted, except for one chapter, to physico-chemical aspects of proteins and their simpler constituents, and, until very recent times, such books have been exceedingly few. The earlier ones by Robertson (1920), Loeb (1922), Pauli and Valkó (1933) were of classical calibre (this one no less), and they were for the most part an interpretation of those properties of proteins directly dependent upon the ampholytic character of the molecule; little was known of the size and shape of the protein molecule. In the last decade, however, we have seen the fruition of Svedberg's monumental researches in this latter field, researches which reoriented the type and scope of physico-chemical research, and we now mark a point at which much is known of what we might call the morphology of the protein molecule, and almost nothing of its fine structure. The present volume incorporates this newer knowledge, yet the emphasis, like that of its antecedents, is upon those properties of proteins arising from their dipolar ionic character. This does not imply a bias: it merely recognizes a fundamental character which makes the protein molecule the great architect of biological reactions.

The outstanding feature of the book is that it presents, both in trend and treatment, the individual approach which Prof. Cohn and his colleagues have consistently followed in the long series of papers from the Harvard laboratories; that is, the properties of proteins reflect in large degree the properties of the simpler peptides and amino-acids, and are explainable, also in large degree, from the more straightforward studies on these simpler compounds. The first part, therefore, is devoted to amino-acids and peptides, thus: spectroscopy and dipolar ionic structure; thermodynamics and simple electrostatic theory; dipolar ions and acid-base equilibria; relations between acidity and chemical structure; dielectric constants and dipole moments; apparent molal volume, heat capacity, compressibility and surface tension; solubility in water and in organic solvents; interactions between organic solvents and dipolar ions; interactions between amino-acids and peptides, etc.; interactions between ions and amino-acids; theoretical interpretation of the properties of dipolar ions in solution.

The second part is devoted to the proteins: structural basis from analysis and proteolysis; X-ray diffraction studies; amino-acid composition; density and apparent specific volume; osmotic pressure and molecular weights; translational diffusion; sedimentation and diffusion; proteins as acids and bases; rotary Brownian movement; electric moments and relaxation times; solubility of proteins; interactions of proteins with ions and dipolar ions; theory of electrophoretic migration.

It must be admitted that the book, though lucidly written, will not be readily assimilated except by the physico-chemical expert, and no review can dismiss that large section of less specialized readers who must enlarge their more purely chemical or biological interests. For the broad mass of workers in the biochemical field—and there are few aspects of biochemistry which do not touch upon and require some knowledge of the properties of proteins—may be deterred by the rigorous mathematical treatment which a book of this nature must embrace. Yet it is important that this section of biochemists should understand, to take one obvious example, the factors governing the solubility of a protein, a knowledge facilitating all preparative and purification techniques in the field of proteins 'proper', hormones, enzymes, viruses, immuno-chemistry and the rest. How far then does the book fulfil the needs of this class of reader? Certainly, Chapters 3 and 12 by Scatchard and by Kirkwood (thermodynamics and simple electrostatic theory; properties of solutions of dipolar ions), and Chapter 25 by Mueller (theory of electrophoretic migration) will not be appreciated and their usefulness must be rather limited. On the other hand, most other chapters are characterized by an unassuming approach and show the adaptation of simple laws to the study of complex problems. Of this, Chapter 4 (dipolar ions and acid-base equilibria) and Chapter 6 (dielectric constants and dipole moments), both by Edsall, are two examples. The authors do indeed create an awareness that they have been sensible of the needs of the less specialized reader, and strike a nice balance between descriptive and mathematical formulation. With a little perseverance, therefore, this class of reader will reap a rich harvest.

We have noted the main emphasis of the book, namely, the dipolar ionic character of proteins. One of the most important sections here is the interaction of proteins and ions, and Chapter 24 reveals that some aspects are not fully understood; particularly the extreme insolubility of some protein cations in presence of mere traces of salt. Again, the interaction of protein with protein must be of great importance in physiological systems, yet few studies have been made. Among other chapters, protein structure is summarily treated, and only a few aspects of denaturation. The treatment of the amino-acid composition of proteins in one chapter is rather inadequate, and the description of some analytical methods, at a time of expansion into the newer chromatographic and biological methods, is not of permanent value. The supplementary index, tabulating the page reference of various types of data for certain amino-acids, peptides and proteins, is extraordinarily useful. KENNETH BAILEY.

MANAGEMENT OF A SPECIAL LIBRARY

Manual of Special Library Technique

With Particular Reference to the Technical Special Libraries of Commercial and Government Establishments. By J. E. Wright. Pp. viii+104. (London: Association of Special Libraries and Information Bureaux, 1945.) 8*s*. 6*d*.

THE discussions devoted to the organization and problems of special libraries and information departments have always been among the most popular at the annual conferences of the Association of Special Libraries and Information Bureaux, and the interest which was aroused by the symposium of papers on the organization of technical information services in industry arranged by the Society of Chemical Industry in October 1943 is further evidence that Mr. Wright's book should have a wide appeal. In contrast to Mr. J. L. Thornton's book on special library methods published in 1940, which was largely a survey of university and university college libraries and those of learned societies and institutions, Mr. Wright's book is a manual of practice, and has particular reference to the technical special libraries of commercial and Government establishments. Within its limits it is a thoroughly competent piece of work. The right points are emphasized and although some of its chapters, for example those on indexing and on classification, may be rather too condensed, it should meet a recognized need. While the manual contains little that is new, Mr. Wright has brought together information which a beginner might not easily trace, and such beginners, as the Association has discovered, are by no means rare.

Most libraries maintained by an industrial firm begin as a small collection of books in a manager's office, with some inflow of trade and other periodicals. Chemical and engineering firms and some others may have enough research interest to acquire some bound runs of the periodicals of the learned societies, and sooner or later the expansion of this nucleus requires a separate room. As soon as even only a small separate room is required, someone is needed to handle the periodicals and take care of the collection, and by this time some special abstracting or card-indexing of particular information may have been requested by busy technologists. The part-time amateur or casual attendant thus finds himself or herself blossoming into a full-time works librarian, and however qualified in knowledge of the manufacturing or scientific side of the firm's business, usually lacks, and is ignorant of, any literature of librarianship as a vocation. Mr. Wright's book is a valuable addition to those published remedies for growing pains of which such beginners are often unaware, and the chapters on the inquiry desk and on information service, based on a paper given to the Association's Conference in 1942, should be particularly appreciated.

For a short manual this book is well balanced, but it would have been better not to have brought in so much reference to ephemeral conditions. In what is presumably intended as a standard and permanent manual, matter relating to war hindrances, if included at all, would better have been relegated to an appendix and discarded at the appropriate time from the subsequent and enlarged editions which will doubtless be called for. The section on patent specifications is excellent, but could with advantage be amplified to include information regarding United States, German, Swiss and French Patent Office publications. In regard to questions of library co-operation, however, Mr. Wright might have made the position of the library of an individual firm a little clearer. In practice, firm's libraries may and often do respond generously to requests for assistance, but such requests are considered on their merits; and it is not clear why Mr. Wright suggests that it is not possible to co-operate in one matter while refusing to co-operate in others. The point is that a firm's library, by its constitution and purpose, cannot offer service outside in the way that a library under public auspices, such as a university library or a Government library, might be expected to do, and this circumstance has to be kept carefully in mind in formulating any large schemes of library co-operation.

R. BRIGHTMAN.

MILK HYGIENE

Bacteria in Relation to the Milk Supply

Third Edition. By G. H. Chalmers. Pp. vii+272. (London: Edward Arnold and Co., 1945.) 8*s*. 6*d*. net.

THE scope of this book has now been clearly defined by this third edition. The book in its present form will without doubt find its greatest value in the hands of students of the methods of milk production, processing and distribution, who require some knowledge of elementary bacteriology. As such the book is extremely valuable, since it is the only modern British text on the subject of hygiene applied to milk handling in all its stages. The section on the control of dairy plant is particularly well done, and collects together all the subject-matter otherwise scattered throughout various text-books, research papers and Government pamphlets.

It must be understood, however, that the book is in no way a text-book of bacteriology, and serious students of dairy bacteriology cannot rely on this volume for any great help in their subject apart from the particular aspects of the hygienic control of production and processing methods and plant. From the systematic point of view it is to be regretted that the existing confusion over nomenclature is increased by such terms as *B. coli*, *B. welchii*, *B. subtilis*, *B. tuberculosis* and *B. cyanogenes*, organisms which, by usual custom, represent five separate genera. It is also perhaps a pity that there is, in the technique of the plate count and coliform test, slight deviations in details from those published by the Ministry of Health. Lack of uniformity in such details renders more difficult the reproducibility of tests already difficult to reproduce.

One further small point: the value of this generally recommended book would be greatly enhanced by the addition of more references to work mentioned in the text.

PHYSICAL CONDITIONS OF THE SURFACE OF THE MESOPHYLL CELL WALLS OF THE LEAF

By PROF. FRANCIS J. LEWIS

Faculty of Science, Fouad I University, Cairo

MOST of the extensive work carried out during the last half-century on transpiration has been mainly concerned with stomatal behaviour and the amount of water vapour passing out from the stomata during their period of opening. Very little attention seems to have been given to the nature of the outer surface of the mesophyll cell walls through which the water vapour passes, and through which at the same time active gaseous exchange takes place.

It has been stated that the surface of these walls is either moist or covered with a thin film of water from which evaporation into the intercellular cavities of the mesophyll takes place. It seemed of interest to investigate the properties of this surface more critically in the light of these suggestions.

The experimental method first employed consisted in cutting leaf strips parallel to the lateral veins. If such strips are suspended vertically with one edge in contact with water, no entry of water takes place into the capillary system, and the same result may be observed if the whole strip is immersed in water. It makes no difference whether the experiment be carried out in light or darkness, and all attempts to induce the entry of water into the capillary system proved unsuccessful.

Experiments were then performed to determine the possibility of the entry of other liquids under similar conditions. Leaf strips suspended vertically over a number of organic liquids, and with the cut end just in contact showed a ready entry of such liquids into the air space system. For this purpose benzene, chloroform, ether, petroleum ether, acetone, essential oils, olive oil and pure medicinal paraffin have been used.

In all these cases immediate entry occurs, the liquid rushing with great velocity into the capillary system of the mesophyll. In the case of benzene, chloroform, ether and petroleum ether a vertical rise of 2 cm. may be obtained in 60 sec., and the rise goes on at a progressive rate until the inflow reaches the upper edge of the strip.

The entry of essential oils, olive oil and paraffin is somewhat slower; but even with paraffin a vertical rise of 5 mm. can be observed to occur in approximately 5 min., and a more rapid rise with the lighter oils.

Direct microscopic observations of the mesophyll surface in relation to the flow of liquids seemed desirable and were carried out in the following manner. The leaf of *Ficus elastica*, by suitable manipulation, can easily be torn transversely, so that considerable areas of the mesophyll are exposed. The lower epidermis with the lower hypodermis readily splits away from the upper portion of the leaf. If the operation be carried out rapidly, no injury to the cells takes place except the individual cell ends of the spongy parenchyma next to the hypodermis. A strip as large as desired, up to 2 cm. in length and breadth, can then be cut off and placed on a slide under the microscope. In this way the whole depth of the mesophyll can be examined under a magnification of 100 or more, and an excellent view of the space system and the small lateral veins be maintained.

A drop of water placed on this surface remains suspended like a lens on the summits of the mesophyll cells and shows no disposition to spread over their surface into the capillary space system. The drop can be enlarged so that it covers the whole strip, but the intercellular spaces still remain non-infiltrated. When a drop of the organic liquids mentioned earlier is used in the same way, instant entry into the intercellular spaces occurs. All these liquids, except medicinal paraffin, have the disadvantage of being toxic and rapidly killing the cells with which they come into contact. While the phenomena to be described do not vary essentially whatever liquid is used, the microscopic observations here described relate solely to the use of pure medicinal paraffin. The use of this hydrocarbon further had the advantage of its behaviour being easily followed, while the entry of the other liquids is so rapid that it cannot be followed by the eye.

When a drop of paraffin is placed at one end of the leaf-strip with the mesophyll surface exposed, the oil immediately penetrates the capillary system. Two advancing fronts can be observed. From the edge of the drop a stream comes out which cascades down into the air space system, and this is followed by the main wave. The outflow cascading down into the air spaces is followed by the main oil wave at a distance of approximately 1 mm., and the oil thus travels the length of the exposed mesophyll in this fashion. When a drop of water is placed about the middle of the strip and oil added at one end of the strip, the oil travels along in the manner described until it comes to the water, and the initial oil wave trickles into the air space system below the water lens and continues its path on the further side.

From these observations it seems clear that while water will not flow over the surface of the mesophyll cell walls or to fill the air spaces, a number of organic liquids do so, and the phenomena can be followed by the use of a non-toxic hydrocarbon such as pure paraffin.

Experiments with Emulsions

If a small quantity of water be shaken up with a much larger amount of paraffin so that the water droplets are of the order of about 0·001 mm. in diameter, and the paraffin with water droplets be placed at one end of a strip of exposed mesophyll, the oil enters the air space system carrying some water droplets with it. It sometimes happens that a water droplet comes into contact with one of the fine veins. When this happens the water droplet appears to adhere to the surface of the vein, often sends out an arm or narrow outflow on one or two sides, loses its spherical shape, becomes flattened, diminishes in size and finally vanishes, being absorbed into the vein. When such a water droplet comes into contact with a mesophyll cell, no change takes place, and, in the absence of a local current of oil sweeping it away, it remains unchanged in position.

When an emulsion of a small quantity of benzene in water is used the behaviour of the mesophyll can be observed microscopically. If leaf-strips be placed in such an emulsion and the containing tube be kept slowly agitated, the ends of the leaf-strips become infiltrated with benzene and the turbidity of the benzene-water almost disappears owing to the absorption of the larger droplets of benzene into the mesophyll air space system. If a similar emulsion be made with paraffin and water and the same conditions be observed, the ends of the leaf-strip become oil-infiltrated. The finest droplets of oil are not absorbed, but only a slight turbidity of the emulsion remains, due to the presence of microscopic droplets.

When a leaf-strip with the mesophyll exposed is prepared and quickly placed on a slide under the microscope, and covered with a cover-glass, moisture immediately collects on the under surface of the cover-glass. It forms at first a system of microscopic polygonal strands of water, giving a minute shagreen aspect to the surface of the cover-glass when viewed under a magnification of 100. After a few minutes the system tends to coalesce. If now water is run in under the cover-glass, it immediately penetrates between the wet cover-glass surface and the mesophyll surface, but does not flow down into the air spaces of the mesophyll. If a drop of oil is placed in contact with the edge of the leaf it immediately passes into the inter-space from end to end of the leaf-strip and is bounded above by the water film still adhering to the cover-glass which, owing to slight inequalities of the surface of the mesophyll, is distant 0·01–0·001 mm.

From these observations it appears clear that while the mesophyll is passing off water vapour rapidly into the air, and this can be condensed on the cover-glass surface in its immediate proximity, the cellulose walls from which the vapour proceeds cannot be wetted, nor does any condensation of water occur on this surface. Under these conditions when oil is presented to the cellulose walls, it immediately flows over them and fills the capillary space.

Infiltration of the Air Space System under Pressure with Dyes

Infiltration under a pressure gradient showed that different dyes have quite dissimilar effects. For example, a solution of Orange G filled the interspace system and coloured the whole infiltrated portion. The same treatment with Methylene Blue resulted in the whole of the dye being taken out of the solution at the point of entry while the clear water proceeds and fills the interspaces. Several preliminary trials of dyes taken at random revealed totally dissimilar effects in different cases, and it was resolved to make an extended series of experiments with a number of biological dyes.

The terms acid and basic dyes, while used frequently in dyeing processes, are sometimes misleading, and from a chemical point of view may be valueless. Every dye contains at least one group of atoms known as a chromophore which is regarded as being responsible for the colouring properties of the compounds in which it occurs. Some chromophores have a basic character and others are acid. On this basis dyes can be classified into acid and basic regardless of the solutions in which they occur. With these facts in mind, all water-soluble dyes available at the time were tested in regard to their behaviour to the surface of the walls of the mesophyll cells by infiltration under a pressure-gradient into the air space system. As a common standard a solution of 1/1,000 gm. mol. was used. The difference in behaviour between the two types of dye can be illustrated by the detailed description of the results given by a basic dye such as Janus Green and an acid dye such as Orange G. When a leaf is infiltrated with Janus Green the whole of the dye-stuff in solution is retained or absorbed on the surface of the mesophyll cells at the point of entry, while the water uncoloured by any dyestuff passes on and fills the interspaces of the mesophyll. The usual method adopted was to cut the leaf in half transversely, connect the cut petiole with a vacuum pump and place the leaf in the dye solution. In this case the whole of the dye-stuff in the solution passing in is adsorbed on the surface of the mesophyll cells within less than a millimetre from the edge of the leaf, while in less than 45 sec. the whole of the rest of the leaf becomes filled with water free from dye. Some objection may be taken to the fact that the solution passes into the space system over a front of cut and injured cells. To avoid this the whole uninjured leaf was submerged in the dye solution, the chamber exhausted. On restoration of atmospheric pressure infiltration takes place from the cut end of the petiole through the air spaces in the cortex. No infiltration takes place through the xylem strand. With this treatment exactly the same phenomena can be observed, for the whole of the dyestuff is adsorbed on the mesophyll walls in a small patch near the base of the leaf while water entirely free from dye fills the interspaces of the lamina. It thus makes no difference whether the dye solution enters the cut edges of a leaf or enters through the cortical interspaces from the petiole; immediate adsorption of the dye takes place in both cases. Microscopic examination shows that the adsorption of the dye is not due to staining of the cell contents but to an actual deposition on the outer surface of the walls. It can further be shown that the dye-stuff enters into a strong combination with the cell wall surface. If the coloured areas of the mesophyll are exposed and placed in water no portion of the adsorbed dye goes into solution; the dye remains permanently held on the surface. Immersion in acetone renders the adsorbed dye soluble and after a short time it may all go into solution and the original green colour of the mesophyll be restored. It is then clear that a dye with a basic chromophore such as Janus Green is strongly adsorbed and held on the outer surface of the cell walls.

If a dye with an acid chromophore such as Orange G be taken, an entirely different set of phenomena occurs. Infiltration results in the dye solution filling the interspaces, and the whole of the infiltrated area takes on the colour of the dye, the outer surface of the walls showing no adsorption of the dye. If now the leaf be allowed to clear itself of the water of the infiltrated solution, which it does in less than one hour in sunlight, the dyestuff is left in irregular patches on the surface of the walls. If the patches are exposed and placed in water the deposited dye immediately goes into solution, showing that it is not held or adsorbed on the surface.

The following dyes with a basic chromogen have been tested: Janus Green, Methylene Blue, Neutral Red, Safranin, Rosanalin, Methyl Violet, Crystal Violet, Methyl Green, Iodine Green, Rhodamine B. These all show the same strong adsorption of the dye by the outer surface of the mesophyll cell walls as has been described for Janus Green. Stains with an acid chromogen such as Orange G, Acid Fuchsin, Methyl Blue, Aniline Blue, Eosin, Erythrosin, all show the same features described in detail for Orange G.

Interesting features are found when the infiltration contains in solution both an acid and a basic dye. In this case the basic dye behaves as described in detail for Janus Green, while the acid dye behaves in a similar fashion to Orange G; so that the leaf is wholly coloured by the acid dye, which enters the interspaces of the mesophyll, while the basic dye is taken out of solution and adsorbed on the surface at the point of entry.

The acidity or the alkalinity of the dye solution makes no difference to the results; the adsorption or the non-adsorption appears to depend entirely on the acid or on the basic character of the chromogen group of the dye.

Action of Fatty Acids on the Wettability of the Cell Wall Surface

Numerous experiments have been carried out with the view of rendering the wall surface wettable by water.

Water containing cane sugar in extremely low concentration has been infiltrated into the air spaces and the leaf allowed to clear itself in sunlight by transpiration through the stomata. This gave no result as water did not enter the air spaces when one edge was placed in contact with water. The use of glycerine also gave no result.

The use of sodium taurocholate suggested itself as an agent for decomposing and penetrating mono-layers of protein. A leaf strip placed vertically in contact with water containing a minute proportion of sodium taurocholate (between 1/100,000 and 1/200,000) immediately showed a rise into the mesophyll spaces and the infiltration proceeded up the strip in the same manner as pure paraffin, but more slowly. After entering for some distance (10–20 mm.) the infiltration stops when a broad band of yellowish brown appears at the margin of infiltration. No further entry of water occurs beyond the band.

At first, experiments with sodium taurocholate showed a ready entry of the water, in other trials it was slight or did not occur at all. Further investigation showed that the *p*H of the solution was important. Solutions decidedly on the alkaline side were inoperative, while a *p*H of 6 and below renders the action certain.

Microscopic observations with sodium taurocholate were carried out on the mesophyll exposed by tearing in the manner described earlier.

If a glass needle be wetted with water containing a slight concentration and a droplet placed on the surface of the mesophyll, after a short interval the water globule begins to spread over the surface and eventually sinks into the lower interspaces in the same way as pure paraffin.

The above observations were carried out on a great variety of leaves. For experiments in which the lower epidermis had to be detached such leaves as *Hyocyamus muticus*, *Ficus elastica*, *Morus*, *Canna*, *Ricinus*, *Malva*, *Pancratium*, *Caryota* proved very suitable. *Hyocyamus* possesses a leaf in which nearly the whole lower epidermis can be peeled off in one operation, leaving the mesophyll cells quite uninjured below. The age of the leaf also influences the ease with which these manipulations can be carried out.

The preceding observations show: (1) that the outer surface of the mesophyll cells are highly hydrophobic; (2) that they are quickly covered by a liquid hydrocarbon; (3) on infiltration with water under a pressure gradient the liquid in the air spaces is quickly cleared when the leaf is placed in strong light, and there is no adhesion to the surface by liquid water; (4) the surface of the walls shows strong adsorption to certain dyes dissolved in water; dyes so adsorbed possess a basic chromophore; dyes having acid chromophores show no adsorption; (5) the hydrophobic nature of the surface of the cell wall is destroyed by sodium taurocholate, which has a lysic action on the protein mono-layers of blood corpuscles.

RECENT DEVELOPMENTS IN AIR PHOTOGRAPHY

By WING-CDR. H. HAMSHAW THOMAS, M.B.E., F.R.S.

THE value of air photography for military intelligence and map revision became recognized early in 1915, and during the War of 1914–18 great progress was made in the design of aircraft cameras. Long series of overlapping pictures were obtained, stereoscopic examination of prints was commenced, and many of the types of information obtainable from suitable photographs were recognized. After that War, the use of this method in survey and map revision was studied[1], and surveys of large areas were made, especially in Canada and the United States. In some places air photographs were employed for scientific studies as I suggested in *Nature* in 1920 [2], and results of importance for geologists, foresters, civil engineers and archæologists have been obtained.

The outbreak of war in 1939 found Great Britain, however, with very inadequate preparations for air photography as one of the chief sources of war intelligence. But during 1940 an organization was brought into being in which many professional men of science were enrolled, and gradually a very strong and efficient service was built up. Later a close co-operation was established with the American Army and Naval Air Services, in which ideas, equipment, materials and methods were interchanged.

The provision of photographs of the areas controlled by the enemy required the use of special aircraft, able to fly deep into enemy country at a height and speed which rendered their interception difficult. This meant the production of special types of our fastest machines, and the training of special pilots to navigate and fly them. The aircraft were generally fitted with two or more cameras, so that the maximum number of useful photographs could be obtained on every sortie. Cameras of the type in service at the outbreak of war were very largely employed, but lens makers were called upon to produce new types of lenses of long focal length for use in them. The general features of these cameras had been designed at the close of the War of 1914–18; they have automatic operation with distant control, and a magazine of film for 250 exposures. As the result of constant research and experiment, many important improvements in the design have been introduced. Later a new type, with a magazine holding 500 exposures, was brought into service, and a somewhat similar instrument designed by the Fairchild Co. in the United States was also used.

The cameras were generally mounted in the aircraft with the optical axis vertical, or slightly tilted so that by the simultaneous use of two instruments greater lateral cover could be obtained. For low-level photographs cameras were installed in an oblique position in the fuselage or under the wings; very valuable work was done with two synchronized cameras facing forwards and giving stereoscopic results. The task of obtaining pictures of specific installations from a low altitude made great demands on the skill and daring of the pilots; it was generally attended by considerable risks.

The operation of cameras at high altitudes produced some special problems, such as the effects of the intense cold on the moving parts, and the occurrence of condensation on the lenses. Special heating arrangements had to be devised to ensure the efficient operation of the cameras at very low temperatures. At low altitudes difficulties were introduced by the very rapid movement of the aircraft. These were solved by the design of new cameras with a moving film. Specially modified types were also needed to secure at night photographs taken by the light of a powerful magnesium flash, or depicting the incendiary bombs dropped by bomber forces and the fires they started.

Photographic chemists have played an important part by producing sensitized films suitable for the work which had to be done, and by devising methods for processing exposed film so that a negative with a very fine grain could be produced in a minimum period of time. In view of all the operating conditions, panchromatic material proved to be the most useful, but infra-red film was sometimes used, and colour film has been recently employed for special tasks.

The production of air photographs whenever the weather was favourable, in sufficient numbers to give a picture of enemies' resources, activities and defences, and to provide the topographical information required by the planning staff, is only one part of the work of photographic intelligence in war. The other part is the detailed examination of the prints and the production of reports on what has been observed. This is often a lengthy and somewhat laborious process. In addition, some of the material may be employed in map revision, or may be used for the construction of models to show the appearance of an area as seen from sea-level or from a low altitude.

For all these purposes pairs of prints are studied with a stereoscope, which gives the observer some measure of appreciation of the relief of the terrain and of the height of objects. Whenever possible, the latest photographs are carefully compared with pictures of the same area taken at an earlier date. This work requires well-trained observers with a good visual memory; they must be able to appreciate the significance of small details, of shadows cast by objects and of changes which may have occurred after a lapse of time. It is often necessary to measure quickly and accurately the sizes of small features seen on the photographs, and from this to determine their actual size. They must be familiar with the appearance and distinctive features of all objects likely to occur on the ground, for reports will not be of full value unless the things that are noticed can be identified. The task of the photographic intelligence officer is thus one of interpretation, and is essentially morphological in character. A very considerable number of men and women who before the War were engaged in scientific research have used their skill and training in this work. Among them were archæologists, geologists, geographers, botanists and zoologists, with some engineers and surveyors; science teachers, artists and many others with suitable intellectual equipment also did valuable work.

Without attempting any complete account of the information gained, some of the subjects investigated may be mentioned. During 1940, after the fall of Dunkirk, the collection of invasion barges in the Channel ports, the movement of enemy shipping, the building of U-boat bases and the construction of airfields in France and the Low Countries were watched. In that year the first air survey of the Ruhr was made; the systematic study of its industrial installations, of oil plants and of the facilities for storing fuel oils in enemy-occupied countries was commenced. At the same period, the results of British bombing attacks on Europe began to be assessed by reference to photographs of targets taken before and after attacks. This work became a task of great importance as the European war proceeded; it served not only as objective evidence of the results of day and night bombing, but it also provided a measure of the efficiency of different types of bombs and of their effect on structures of different kinds.

Suitable annotated photographs of target areas were needed by bombers using the 'H2S' radar equipment. After the Germans had attacked the U.S.S.R., and their armies in Western Europe assumed a defensive role, regular photographic reconnaissance was needed to follow the building of coastal defences. It became possible to give a full report at any time of the state of the enemy's positions along the coast from Holland to the Spanish frontier. Much of this information was used in the planning of commando raids. Detailed study was also given to the building of radar stations by the Germans after the initial discovery of their first station from photographs taken in November 1940. This work required the most careful examination of thousands of photographs and a minute study of all suspicious objects. When a new station had been located on high-altitude pictures, pilots were often able, with great daring, to obtain oblique views from a low altitude which would show the external details of the installation.

As time passed and plans began to be formulated for landing the Allied armies in North Africa, Italy and Normandy, the demands for military information of every kind became enormous. Not only was it necessary to determine the positions and types of the enemy defences and his strength in armoured fighting vehicles, but also to obtain exact information about the characters and gradients of beaches, the nature of the adjoining terrain, of the woods and thickets, the roads, rivers and bridges, and about many other things which might affect the success of a landing. Photographs and the models made from them played a very important part in the preparations for every great offensive action.

Photographic intelligence also played a noteworthy part in naval operations. It was of great assistance in showing the positions of German naval units throughout the War. The location of the battleship *Bismarck* in a Norwegian fjord in 1941 and the subsequent events will be remembered. After long and careful study it became possible to identify in photographs each of the merchant ships used by the enemy and to follow their movements from port to port. Shipbuilding and submarine construction were kept under regular observation and the knowledge obtained assisted the defence of our merchant navy. The method of calculating the speed of a ship, by the study of the waves seen when it was photographed at sea, is an interesting example of research carried out by interpreters with a physical and mathematical background; it had important operational results.

As the years of war passed, some of the research groups of intelligence officers were confronted by problems of considerable difficulty. They had to report on objects which did not exist before the War, and the real nature of which could only be inferred from their appearance. The description and identification of such things required careful observation and scientific reasoning. The radar stations already mentioned were of this class; another example was decoy installations built in Germany with the object of drawing off the attacks of Allied bombers from specific targets. Many of these decoys of different forms were located and described after a long period of study.

A subject which occupied the attention of a small group of specialists was the production of synthetic petrol and other oil. A considerable number of new plants were built after the War had commenced, while the older ones were enlarged or extended. The first problem was to locate the new plants, and after this had been done they had to be studied to discover the processes used and their probable designed capacity. The estimation of the oil resources of the enemy during the later years of the War depended very largely on the reports of this group, which had also to ascertain the effects of bomb damage on production, and to forecast the time which would be taken in the repair of damage. It has been lately learned that the Allied attacks on oil contributed largely to the collapse of the enemy, and these attacks depended to a very large extent on photographic intelligence. The production of synthetic rubber in Germany presented a somewhat similar but still more difficult problem.

It is interesting to notice that photographic reconnaissance showed that a most extensive exploitation of the brown coal deposits of Central Europe had been made for the production of electric power, tar and fuel of different kinds. Very few people in Britain seem to realize the importance of brown coal in the economic life of Germany.

Aircraft construction must be mentioned among the industries which received special study. The appearance of new types was often first announced after the examination of photographs; the development of the jet-propelled Me.262 was recognized in this way.

Of all the tasks carried out by pilots and interpreters of Allied photographic units none was more exacting or more vital than the investigation of the enemy rockets and flying bombs. During the summer of 1943, photographs provided objective evidence of these weapons and showed the places where they were being developed. The successful attack on Peenemunde which followed these discoveries caused a postponement by several months of the launching of the missiles against England. Afterwards, the location of a large number of firing sites in northern France was successfully accomplished, and the accurate bombing of these military installations still further delayed their employment. The enemy then proceeded to construct firing points of a new type which was less obvious from the air, but it was not very long before more than a hundred of these were located. When firing eventually commenced, Allied bombers were able to reduce considerably the projected weight of attack. Attention was also paid to the places where the missiles were manufactured and stored. In the course of the fight against the 'V' weapons, considerably more than a million photographs were taken and examined.

In the Mediterranean area and the Far East, air photography has played an important part to which no reference can yet be made. The production of modern military maps, a most vital service in the warfare of to-day, needs a separate article to show what has been done. Air survey has provided much material for this work; the photographs have been used in different ways, sometimes after the methods worked out by the British Air Survey Committee, sometimes by the rapid methods practised in Canada before the War, sometimes with the help of the Wild Autograph or by the Zeiss Multiplex method.

From all this co-ordinated effort, there should be some legacy capable of useful employment in a world at peace and for scientific work. A vast library of photographs of Western Europe and of other areas now exists in which are numbers of photographs of interest to scientific workers. It is to be hoped that these will be made available for study, and that they will not be destroyed as after the War of 1914–18. Once again we have seen the great value of the air method of determining in great detail the positions of objects on the ground. The use of this method would make possible the study of physical features, of the distribution of vegetation, of the location of antiquities, and many other things which cannot be investigated by ground survey because of the vast labour involved. Attention has already been directed in *Nature* of July 7, p. 2, to the scientific advances which may well result from the continuation of air survey by the R.A.F. in time of peace, and the matter needs careful consideration by the appropriate authorities. The history of air photography in Britain shows how the Fighting Services may suffer if organized units of the R.A.F. are not maintained for this work in the future. But efficiency can only be kept up when there is important work to be done, and Service personnel know that when they carry out good work it will lead to results of permanent value.

The work steadily pursued in Canada between the two Wars should be more widely known. It provides an example of the beneficial results of air survey for civil purposes, while affording experience of the greatest value in case of war. Great areas have been mapped by the Dominion air surveyors, and it may be recalled that so early as 1924 the Forestry Department sent photographs, which were shown at the Empire Exhibition at Wembley, illustrating the practical value to foresters of this work.

Scientific workers have always stood for the value of research even though its immediate practical value cannot be demonstrated, and the same view may be taken of air survey. Only those actively engaged in the detailed geological investigation of the upland areas of Britain know how this work is restricted by the lack of detailed topographical maps. Air photographs would easily remedy this deficiency. In the same way the problems of changes in coastal lands, the study of land utilization as well as town and country planning, could receive immediate help from an organized national photographic reconnaissance unit the results of which were kept in a library similar to the Canadian National Library of Air Photographs (now known as the National Topographical Library, of the Department of Mines and Resources) at Ottawa.

In 1939 few people, either in the Services or in civil life, realized the potentialities of air photography or the part it was destined to play in the great European struggle. The brief account which has been given above should remind us that it may in the same way prove to be of unforeseen value in times of peace.

SEX EDUCATION: AIMS, POSSIBILITIES AND PLANS*

By CYRIL BIBBY

IT is sometimes forgotten by many educationists to-day how much is owed to the pioneers in the field of sex education. Whatever differences of opinion there may be about the desirability of the specific measures they recommended, it is clear that the great advance in sex education which is taking place to-day could not have occurred if they had not prepared the ground. As a result of their work, views that were novel and unorthodox are now almost commonplace and acceptable even in official circles.

Perhaps the greatest turning point on this path towards official recognition was the transference in 1942 of the major part of the work of the British Social Hygiene Council to the Central Council for Health Education. What this official support has meant to the cause of sex education is perhaps best illustrated by some figures. The numbers of sex education lectures given by these two bodies to certain types of audience during the past five years are as follows:

AUDIENCE	1940–41	1941–42	1942–43	1943–44	1944–45
Teachers	7	95	83	86	232
Youth leaders	17	35	33	59	118
Parents	21	39	37	75	117
Young people	257	612	580	1,348	1,416
School children	71	87	101	208	159

The total attendance at these meetings during 1943–44 was 68,712 (the figures for 1944–45 being not yet available) while, if the audiences at meetings and film shows on venereal diseases are included, the total attendance during the year was some 300,000. Quantitatively, then, the present position is fairly satisfactory. The number of people who have received *some sort* of sex education during the last five years is considerable.

It is clear that there has been of recent years a radical and widespread change of public opinion on the question of sex education. The time has passed when it was necessary to state with some vehemence the case against sheer obscurantism. Probably there will remain with us for many years a few frightened adults who will continue to foster the cult of ignorance; but an increasingly large section of the population is allowing the myths of the gooseberry bush and the stork to fade into oblivion. The general public, educational and medical administrators, churches and social organizations, teachers and youth leaders, parents and pupils—all are ready to go ahead. No longer is it necessary to press the claims of sex education in language more vigorous than profound. Now is the need for careful study of the many educational issues involved. Only after such study is it likely that the position in sex education will be at all satisfactory as regards quality.

The first issue for study is that of objective. What are the aims of sex education and what are its possibilities? To serve as a basis for useful action, an objective must be desirable, attainable and sufficient—and this cannot be said of some aims that have been propounded.

There are, for example, those who use 'sex education' as an euphemism for dilation on the horrors of venereal disease, and hope to frighten young people into 'goodness'. But sex education is not mere anti-venereal propaganda; it is preparation to live a joyous, well-balanced and fruitful life. There are others whose aim is to produce 'morality' by threats of fire and brimstone. But the educationist can have no concern with such 'goodness' and such 'morality'. Such aims fail on the test of desirability.

Other aims, perhaps desirable enough in themselves, fail on the score of feasibility. To expect by sex education alone to wipe out prostitution and casual promiscuity, to make all marriages successful and all divorces disappear, to abolish adultery and prevent all fornication, is to be hopelessly unrealistic. Many and deep seated are the sexual ills of society, and education unaided will not eradicate them. Economic and political changes and a new social and spiritual vision are needed too.

Now what of the criterion of sufficiency? A great many people seem to imagine that sex education consists merely of imparting the so-called 'facts of life', although one would have thought that the inadequacy of this conception were sufficiently clear. A study of ancient or contemporary history, or even a superficial knowledge of the lives of one's acquaintances, will rapidly dispel any illusion that there is necessarily a close correlation between the extent of an individual's biological knowledge and the excellence of his actions.

The teaching of the obvious biological facts will make it clear to our children that the human sex organs are essentially similar to those of other mammals, such as the rabbit; and if sex education were to stop there, it would be logical for a child to deduce that the sexual behaviour of a healthy young human should not be very different from that of a healthy young rabbit. But since presumably we do not wish to adopt the rabbit as the model for our sexual behaviour, sex education must at the appropriate stages deal also with those respects in which humans *differ* from the other mammals, and in particular with the consequences of the unique development of our nervous system and of our peculiar sociability.

But still something else is needed. Our children must be inspired with a feeling of the excellence of sex and of its immense potentialities. Our young people, if they are to deny themselves the immediate sensual pleasures with which our bodies can so richly provide us, must see some reason for such a sacrifice. If they are to be asked to wait, they must feel that they have a future, and a future that is worth waiting for. If society is to make demands, it must see to it that its members think sufficiently highly of it to be willing to accede to them. Behaviour is dependent upon ideals and inspiration, as well as upon factual knowledge and intellectual understanding.

It is, however, easy enough to criticize aims expounded or implied by others. Much more difficult is the task of formulating a statement to take their place. I do not feel sufficiently confident to do so at all dogmatically; but at any rate a tentative effort should be made. I would, therefore, define the aims of sex education something along these lines: "That our people should grow up learning the appropriate facts in the best possible way; that their general attitude to sex should be a completely healthy one; that they should draw up for themselves a code of conduct after careful consideration of all the issues involved and should endeavour to behave according to this rationally determined code; and that they should react to the behaviour of others with sympathy, tolerance and charity, but without spineless acquiescence in a code inferior to their own." No doubt this statement of aims could be much improved, but it will serve as a working basis for the time being.

---

* Substance of an address at the annual general meeting of the Eugenics Society on May 29. The paper will be published in full in the *Eugenics Review*.

First, what constitutes 'appropriate' knowledge and at what age should it be imparted ? This latter query is clearly one to which there is no simple answer. No one age can be prescribed for sex education, any more than it can for any other aspect of health education or character training. Sex education should surely be a continuous process from early years to later life, and the question should really be re-phrased to read : What aspects of sex education are particularly appropriate to different ages ? This is obviously difficult to answer in general terms, for no one human is exactly like another; but if we call to our aid that mythical creature the 'average' person, a reply may be attempted.

I would suggest that by about the age of two or three years, children should be learning the polite terminology for the sex organs, just as they learn the words 'arm', 'leg', and 'head'. By the time they go to school at about five, they should in most cases know that the baby grows inside the mother and is born *via* an opening between her legs ; and should understand something of the similarities between birth in humans and in the domestic mammals. During the next two or three years the child should learn that the father contributes the sperm cell which fertilizes the mother's egg, and that the penis is placed in the vagina during mating.

These apparently dogmatic statements about the order in which information should be imparted are not made without reason. The suggested order is that indicated by analysis of the questions typically asked by children of various ages. Questions about birth and pregnancy tend to be asked first of all. It is usually only later that the child inquires about the role of the father, and thus elicits explanations of fertilization and copulation. My belief is that, in general, the right time for enlightenment is when the child seeks it—not when some adult thinks that an appropriate age has been reached.

There are some things, however, in which the adult must act as pacemaker, because the adult knows what sort of ground lies ahead and the child does not. Some time from about the age of twelve onwards a girl will begin her menses, and she needs to be prepared in advance by a simple biological explanation at the age of about eleven. Boys also should have an idea of the significance of menstruation, so that they do not build up on a basis of ignorance an atmosphere of mystery about their sister's periods. But more important for boys is a preparation for the changes that will occur in themselves during adolescence, and in particular for the onset of seminal emissions which, accompanied as they often are by erotic dreams, cause adolescent boys a good deal of needless worry. Minds worried and terrified by the outrageous allegations which still circulate about the alleged ill-effects of masturbation need also to be set at rest—or, better still, so fortified by the truth that the worries and fears never materialize.

So far no mention has been made of any other than the reproductive aspect of sex, and there is, I believe, good reason for this. It is clear from their whole attitude that most children of less than about twelve years (or even older) think of sex as a purely reproductive matter, and have no conception of its amatory aspect. During the three or four succeeding years, however, the endocrine changes of adolescence begin to produce deeper sexual feelings ; an understanding of the love aspect of sex begins to dawn and, with it, an interest in the morals and social conventions of sexual behaviour. This, therefore, I suggest is the period when a point should be made of explaining something more of the influence of the endocrine secretions on the body and the emotions. This, too, is probably the best time for discussing questions such as courtship and marriage, 'necking and petting', promiscuity and prostitution ; and for imparting the elementary facts about the venereal diseases.

Towards the end of adolescence and in early adult life, general sex education merges into specific marriage preparation and guidance—a topic too large to consider in any detail now. It may be suggested, however, that apart from a knowledge of the actual technique of intercourse, sex education during the courtship stage should emphasize the importance of each partner understanding well the emotional peculiarities of the other and exercising delicacy and restraint in whatever degree of love-making may be mutually agreed upon. Couples contemplating marriage should be encouraged to learn something of each other's physical and mental health ; to understand the economic implications of marriage and parenthood ; to reach agreement on how their future home is to be run ; and they should be informed of the sources to which they can turn for further information and guidance.

Sex education, however, should not end with marriage. Apart from any continuing guidance in the technique of intercourse, I believe that all married couples should have some training in child care and parentcraft and—of particular relevance here—should be given some understanding of the normal sexual development of children and of how to cope with the problems arising from it. Here, however, the sex education of one generation merges into that of the next ; and perhaps we had better leave the matter for the time being.

The next problem is that of the encouragement of a healthy attitude to sex, and this is a difficult matter—partly because there is by no means unanimity about what in fact constitutes a healthy attitude. I can do no more, therefore, than register my own personal *credo*.

It seems clear that on impressions gained and attitudes formed in the first five years of life depend to a considerable extent the emotional balance and happiness of the adult. Let us, therefore, examine some of the factors influencing these impressions and attitudes. Because of the close physical proximity and nervous connexion between the voiding and the genital organs, attitudes developed with reference to the former are likely to be transferred to the latter. Any feeling of distaste for the process or the products of voiding may, therefore, have a decidedly unfortunate influence on later feelings about sex. Thus it is patently important not to encourage such feelings ; but on the contrary to convey the impression that voiding, like eating, is a perfectly normal and proper process.

Then there is the question of the so-called 'infantile masturbation'. It is unfortunately the case that many parents, mistaking the exploratory path of innocence for the broad highway of incipient vice, either tell the child not to be 'nasty' or 'rude', or by some action show their disapproval. What is the poor infant to think, that it may safely pull its nose and may twiddle its toes with impunity; but if it does the same in a region half-way between, it incurs displeasure? Clearly there is nothing better calculated to encourage the feeling from the earliest days, that there is something quite isolated from the rest of life, something unclean, about the sexual organs, and hence at a later date by association, about the sexual functions. This too, therefore, must be avoided.

Now, what of the question of nudity? It is a commonplace that attitudes to sex are often associated with similar attitudes towards nudity, so if a child from the first learns to regard nudity as in no way an indecent phenomenon, it is reasonable to hope that it will be helped in the development of a healthy attitude to sex. Naturally, however, children must, to save both themselves and others from embarrassment, learn as they grow up that there are occasions and places, including most public occasions and public places, in which nudity is frowned upon.

A great opportunity for encouraging a proper attitude to sex occurs when another child is expected in the family. By careful preparation on the part of the parents, a sense of pleasurable anticipation may be aroused in the children and crowned with a feeling of family solidarity when the baby arrives, and that surely is the goal to aim at.

During these early years, moreover, there are certain attitudes not specifically sexual in nature which are, nevertheless, of fundamental importance in laying the foundations for a successful family life in later years. I have in mind the development of habitual friendliness to the other members of the family, of affection and consideration for others, of willingness to share possessions and to co-operate amicably in activities with playmates. I have in mind also the growth of interest in, and of a sense of wonder at, the workings of Nature, the growth of an æsthetic sense, of a desire for personal health and cleanliness, of admiration for vigour and smartness, of distaste for furtiveness and dishonesty. Sex education, indeed, interpenetrates indissolubly with general character training.

With the onset of adolescence other more specifically sexual attitudes become important. One should endeavour to arouse a sense of pride in approaching maturity. It is important also that each sex should develop an attitude of sympathetic consideration to the other, regarding friendships as perfectly natural and quite desirable, but as needing the exercise of discretion and restraint. This is the period too, I suggest, when one should particularly endeavour to encourage an attitude of distaste for obscenity and pornography—without, however, going to the other extreme of prudery or priggishness. There are those, I know, who believe that sex is so sacred that it should never be the object of humour. For my part, I *do* feel that certain aspects of sex and sex behaviour are sometimes rather ludicrous, that sex *may* sometimes quite properly be the occasion of humour; and I would therefore emphasize the importance of avoiding the sin of hypocrisy. The distinction to make is surely that between hearty, unashamed laughter and nasty, shamefaced sniggering; between something which is funny and incidentally sexual and something which is merely filthy in nature.

By the time adult life is reached, basic attitudes are already largely determined. It is important, however, if the idea of sex education is to be widened, as I believe it should be, into a conception of education for family life, that we should devote attention to encouraging those contemplating marriage to be willing to discuss reasonably and in a friendly spirit, such matters as the economic running of the home, the division of domestic duties, family planning and so on; and that we should endeavour to ensure that married persons should be considerate in all things towards the spouse, should not regard the wedding ceremony as terminating the period of courtship; should have a proper attitude to the upbringing of their offspring. But once again we have made the circle, and have reached to the next generation.

(*To be continued.*)

OBITUARIES

Mr. W. Sydney Smith, C.B., O.B.E.

William Sydney Smith was a native of Nottingham. He was born in 1866, the eldest son of Samuel Smith, of the firm of Sydney Smith and Sons, engineers. Educated at Nottingham High School, where he excelled in class and in sports, at the age of sixteen he was apprenticed to a Nottingham engineering firm. During his apprenticeship, while working from 6 a.m. to 5.30 p.m., he attended evening classes, an early indication of his grit and determination. He first intended to take up teaching, but winning in 1889 a Whitworth Exhibition of £100, he decided to follow the family tradition of engineering, and taking his B.Sc. (London) degree, in 1890, he joined his father in his engineering business for a short time. He then went to an electrical engineering firm at Westminster, and on, for a while, to Willans and Robinson at Thames Ditton, returning to his father's firm in 1893.

On the death of his father in 1895, Sydney Smith sat for a Home Office examination and was appointed one of H.M. inspectors of factories, going to Manchester in 1896 and from there in 1905 to Derby. While in Manchester he compiled a 'blue book' on hoists and lifts. In 1908 he was appointed H.M. inspector of dangerous trades at the Home Office.

Early in 1918 the late Sir Henry Fowler, who had known Sydney Smith at Derby and had a high opinion of his personal qualities and his engineering ability, recommended him as his successor as chief superintendent of the Royal Aircraft Establishment at Farnborough, Hants, and he served there until his retirement in 1928.

Though having little aeronautical experience, Sydney Smith quickly grasped the essentials of the work of the Establishment, and he keenly encouraged all steps to improve its effectiveness as the main centre of aeronautical research, and to make its resources, and the results of its work, readily available to the aircraft industry. The period of his work at the Royal Aircraft Establishment was not an easy one; after the change from a war economy to that of peace, the further retrenchment in Government expenditure necessitated the discharge of a large number of the employees. He was a great friend of the staff and workpeople, to whom he was endeared by his obvious integrity, his strict fairness to all and his sympathy and consideration for their welfare; and it was very painful to him to have to discharge men at a time when employment was not easy to obtain.

His work at the Royal Aircraft Establishment was recognized by the award of the O.B.E. in 1918 and C.B. in 1922.

Sydney Smith had a great habit of early rising, and usually spent an hour or two before breakfast working in his garden, which was his chief relaxation. He was an ardent supporter of improvement in educational facilities both for the trade lads within the Establishment and in the provision of a junior technical school and evening classes and a secondary school in the district.

His garden and his local activities (among other things he was a member and vice-chairman of the Surrey N.W. Area Assessment Committee) gave him satisfying occupation during his retirement, until his strength gradually failed and he died at his home, "The Pines", Camberley, on July 15, 1945.

He married in 1907, Hilda Mary, the daughter of William Charles Tuke, of Manchester, who, with three daughters, survives him.

WE regret to announce the following deaths:

Miss Lucy Ashcroft, formerly lecturer in mathematics in the University of Reading, on September 30.

Prof. A. E. Edgecombe, associate professor of botany in Northwestern University, Evanston, Illinois, known for his work in mycology, on March 30, aged forty-eight.

Peter Esben-Petersen, a Danish authority on the systematics of neuropterous insects, on April 2, 1942.

Prof. E. Shearer, formerly professor of agriculture and rural economy in the University of Edinburgh and sometime director-general of the Ministry of Agriculture, Egypt, on September 14.

Prof. E. J. Williams, F.R.S., professor of physics in the University College of Wales, Aberystwyth, on September 29, aged forty-two.

NEWS and VIEWS

Prof. Norman Feather, F.R.S.

DR. NORMAN FEATHER takes up his appointment as professor of natural philosophy in the University of Edinburgh this session. Dr. Feather has held the appointment of lecturer in physics in the University of Cambridge since 1936; he was elected to a research fellowship of Trinity College in 1929, and to a staff fellowship in 1936. After taking the Natural Sciences Tripos in Cambridge, Dr. Feather took up research work under Lord Rutherford in 1927 and worked first on the long-range α-particles from radium. He spent a year at Johns Hopkins University in Baltimore, and there studied the relations between β-particle energies and absorption coefficients, deducing therefrom a much used empirical relation. Returning to Cambridge in 1930, he resumed work with the Wilson cloud chamber, and in 1932 was brought in by Dr. J. (now Sir James) Chadwick to obtain cloud chamber confirmation of his discovery of the neutron. Within a few weeks, Dr. Feather was able to obtain tracks resulting from neutron collisions and, in particular, was able to demonstrate the disintegration of nitrogen by neutrons. This was the first evidence of disintegrations produced by neutrons.

In 1935 Dr. Feather joined Prof. Chadwick, who had in the meantime been appointed to the chair of physics in the University of Liverpool, and for two years helped to build up the physics research facilities there. During this period, Prof. Chadwick and he studied the photo-disintegration of deuterium. He returned to Cambridge as lecturer in physics and staff fellow of Trinity College. He then took up the study of nuclear energy-levels by the coincidence methods of counting which have since borne good fruit. Dr. Feather is the author of a biography of Lord Rutherford and a treatise on radioactivity. In the early days of the War, along with the rest of the Cavendish Laboratory staff, he headed a party manning a south-east coast radar station. He returned from there to shoulder a major share of the teaching and administrative duties of the Cavendish Laboratory and, early in 1940, under the sponsorship of the M.A.U.D. Committee of the Ministry of Aircraft Production, took up work with Bretscher on the measurement of nuclear cross-sections required to establish the feasibility and size of an atomic bomb. He has since been a member of the British technical committee which has directed the work of the British group concerned with atomic energy.

Anatomy at University College, London
Appointment of Mr. J. Z. Young, F.R.S.

THE appointment of Mr. J. Z. Young, demonstrator in zoology in the University of Oxford, to the chair of anatomy at University College, London, provides an interesting departure from the normal practice in Great Britain in filling chairs of anatomy. Tradition in this Department at University College, deriving largely from Elliot Smith's wide range of activities, favours a broad conception of the field of anatomy which is thus likely to be continued. Prof. Young's work before the War on the nervous system of many species and his fruitful collaboration with clinical colleagues on the Nerve Injuries Committee of the Medical Research Council during the War suggests, further, that the especial emphasis on neurological anatomy associated with the work of Elliot Smith and Woollard at University College, London, is to be maintained. Experience gleaned in unusual fields should enable Prof. Young to bring fresh and arresting ideas to the current reconsideration of preclinical training, and new developments in the teaching of anatomy may confidently be anticipated.

Prof. R. P. Linstead, F.R.S.

PROF. R. P. LINSTEAD, whose appointment as director of the Chemical Research Laboratory, Teddington, has just been announced, was educated at the City of London School and at the Imperial College of Science and Technology, where he had a brilliant career. He graduated in 1924 and entered J. F. Thorpe's flourishing school of organic chemistry, working with G. A. R. Kon on three-carbon tautomerism. After obtaining the degree of Ph.D. in 1926, he succeeded Kon as private assistant to Thorpe, a post which enabled him to devote all his energies to research. During this period he worked out a method for the estimation of isomeric unsaturated compounds in mixtures, which enabled considerable progress to be made in the study of unsaturation and of tautomerism of unsaturated compounds. He obtained the degree of D.Sc. in 1930. Linstead spent a year away from academic work with the Anglo-Iranian Oil Co., then returned to the Imperial College as a member of the staff and remained there until 1938, when he accepted the Firth chair of chemistry at the University of Sheffield. He moved to Harvard in the following year, but was soon afterwards seconded for service with the Ministry of Supply, where he acted as deputy director of scientific research.

Prof. Linstead's scientific work is characterized by remarkable thoroughness and breadth of view; he is clearly not interested in quick returns and likes to tackle problems of fundamental significance. His best-known contributions include studies of unsaturated acids, carbocyclic fused-ring compounds and the discovery of a very interesting new class of synthetic pigments, the phthalocyanines; his recent investigation on the stereochemistry of catalytic hydrogenation is a particularly finished piece of work. Prof. Linstead, who is forty-three, was elected a fellow of the Royal Society in 1940 and is an honorary M.A. of Harvard University.

Wellcome Museum of Medical Science: Appointments

WING-COMMANDER C. J. HACKETT has been appointed director of the Wellcome Museum of Medical Science in succession to Dr. S. H. Daukes, who has been responsible for the development of this Museum during the last twenty-six years. Dr. Hackett, who was a research fellow in tropical medicine of the Medical Research Council and who has done important work on yaws and other tropical diseases, will take up his new appointment as soon as he has been released from the Royal Air Force.

Dr. E. Ashworth Underwood has been appointed director of the Wellcome Historical Medical Museum and the Wellcome Historical Medical Library, and will take up his new duties as soon as he can be released from his present post of medical officer of health and chief school medical officer of the County Borough of West Ham. Dr. Underwood has held his present post for the past eight years. Before that he was medical officer of health of the Metropolitan Borough of Shoreditch, deputy medical officer of health of the city of Leeds, and lecturer in public health in the University of Leeds. In this field he has written widely on tuberculosis, on epidemiology and allied subjects. Dr. Underwood is well known for his activities in the sphere of the history of medicine. During the past five years he has been honorary secretary of the History of Medicine Section of the Royal Society of Medicine. He has contributed to the *Proceedings* of that Society, and to other journals, studies on the history of certain infectious diseases, on the medical importance of Lavoisier and the French chemists, on the earlier anatomists and on other subjects. He has for some time been collaborating with Prof. Charles Singer in work on Vesalius.

National Research Council (Canada)

THREE new members have been appointed to the National Research Council (Canada) and two other members have been reappointed. The new members are: Mr. Percy Bengough, president, Trades and Labour Congress of Canada, Ottawa; Dr. Paul Gagnon, director, Department of Chemical Engineering, Laval University, Quebec; and Prof. David A. Keys, Macdonald professor of physics and chairman of the Physical Sciences Group of the Faculty of Arts and Science, McGill University, Montreal. The two members reappointed are Prof. J. A. Gray, Chown science research professor, Queen's University, Kingston, Ontario, and Mr. Arthur Surveyer, consulting engineer, Montreal, Quebec.

Scientific Co-operation with Czechoslovakia

SIR ALFRED EGERTON, one of the secretaries of the Royal Society of London, has left for a visit to Prague to convey the greetings of the Royal Society on behalf of the men of science of Great Britain to their colleagues in Czechoslovakia. He will be the guest of the rector of the Charles University in Prague and will discuss with him and his colleagues what aid British science can give to the rehabilitation of science and scientific education in their country. It is hoped that this visit may do much to enable the people of Czechoslovakia to re-establish firm scientific contacts with men of science throughout the world. Sir Alfred Egerton is taking with him, for the Masaryk University at Brno and the Royal Bohemian Society of Sciences at Prague, scientific publications of the Royal Society issued during the war years.

Czech Botanists During the War

BOTANICAL research, like that in other branches of science, almost ceased in Central Europe when the Germans marched in. With their laboratories closed, Czech botanists retreated to their gardens and homes, where they had the leisure in which to examine the results of previous researches, conducted before such work was interrupted. Prof. Bohumil Němec, already the author of several standard Czech botanical works, wrote a comprehensive treatise on "Plant Life", in which he used more than seven hundred original illustrations. In addition, he published a more popular work, "The Green Kingdom", and also articles dealing with the mechanism of plant growth, movement and reproduction for biological and scientific journals, which seem to have increased in importance as the nation's position became more desperate. Dr. S. Prát continued to publish sections of his "Rostlinopis", a kind of botanical encyclopædia inspired, apparently, by the work a hundred years ago of those two pioneers of botany in Bohemia, the brothers J. S. and K. B. Presl, who used the same title for their "Botany", which they did not live to complete.

In mycology, Dr. J. Peklo published several long papers (including a seventy-page monograph) on the genetics of certain fungi and the problem of 'relative sexuality' among lower plants. As these contributions to botany are written in Czech they will not receive much attention until detailed abstracts are available in English. Not all Czech botanists were fortunate enough to remain unmolested. Prof. Němec's son was obliged to hide in the forests of Slovakia, and the exposure has impaired his health. Dr. Augustus Bayer, professor of botany in the Masaryk University of Brno, was executed by the Germans in 1942. He was a specialist on the development and anatomy of wood tissues. Dr. Bayer, who was sixty years of age, had also been engaged upon problems in forestry and agriculture, and indeed had gained an international reputation as an expert in applied botany and dendrology.

Jubilee of the Newcomen Society

THE next meeting of the Newcomen Society, to be held on November 14, will mark the completion of twenty-five years activity of the Society. The officers of the Society in 1920 included A. Titley as president, three vice-presidents, ten members of council and H. W. Dickinson as honorary secretary and treasurer; of these fifteen members, seven have served on the Council during the whole twenty-five years, Dr.

Dickinson serving as sole or joint honorary secretary for the whole period except for the two years of his presidency 1932–34, when A. Stowers took office. The growth of the Society can be traced in successive annual reports published in the *Transactions*. The first volume of *Transactions*—that published in 1922—occupied 83 pages, and contained six papers and a list of 120 members; volume 20, 1939–40 (the last before the War), exceeded 180 pages and contained twenty papers, while the annual report gave the membership as 1,512. Since then the membership has risen to more than 5,000, principally due to the activities of the American members. Besides the papers, the *Transactions* have contained a valuable analytical bibliography of the history of engineering and applied science. The Newcomen Society owes much to Dr. Dickinson for his long service as secretary, and also for his editorship of nearly every volume of the *Transactions*. It has, therefore, been decided to invite subscriptions to a Dr. Dickinson Presentation Fund, the proceeds from which will be given to Dr. Dickinson in the form of a cheque or be expended on objects chosen by him. The upper limit for subscriptions is fixed at £2 2*s*. Members wishing to subscribe are asked to send their subscriptions, not later than October 10, to the assistant secretary, Miss G. Bingham, O.B.E., 43 King's Road, Chelsea, S.W.3, made payable to the "Dr. Dickinson Presentation Fund". Dr. Dickinson will be entertained to dinner after the annual general meeting on November 14, when the presentation will be made.

University and Research Libraries

The University and Research Section of the Library Association held its first week-end conference since 1938 on September 21–24 at Wadham College, Oxford. The Conference was well attended, and visits were paid to many of the Oxford college and other libraries. The general meeting of the Section held on September 22 and 23 was concerned chiefly with the discussion, amendment and final approval of the Committee's proposals for the post-war development of university and research libraries. As soon as they are approved by the Library Association Council, they will be issued to the general public. Reference has already been made in *Nature* (Dec. 11, 1943, p. 687; February 19, 1944, p. 203) to these proposals which are intended to ensure an adequate supply of books and other materials for the prosecution of research in Britain. They deal with the place of university and research libraries in a national system, the national and local organization for research, administration and staffing, and plead for the fullest co-ordination of all library facilities. But this cannot be achieved until the national library resources have been comprehensively and qualitatively surveyed, a long overdue piece of bibliographical research. The programme of such a survey has been prepared by a committee of the Section's and it is hoped that funds will eventually be forthcoming for the project.

M. Henri Lemaître, a vice-president of the Library Association and formerly librarian of the Bibliothèque Nationale, was unable to attend through illness to deliver his promised address. Fortunately, a copy had arrived, and was translated and read to the session. M. Lemaître outlined the story of French libraries and librarians during the German occupation, a record of destruction and racial discrimination. During 1940–45, more than two million books were lost through the ravages of war, many of them forming the irreplaceable local collections in which France abounded. Many thousands of books, including complete libraries, were seized by the Germans. Yet French librarians stood firm against all threats, and continued to serve their readers to the best of their ability. In their private lives and in their professional occupation they were in the van of the struggle against the Nazis, and many suffered imprisonment and death for their devotion. Despite Nazi opposition they maintained a supply of books to French prisoners of war. They continued to supply books on the various proscribed lists to trustworthy readers; and when liberation came, they were ready with their plans for rehabilitation with the creation of new book centres for the French people on the lines of the English county library system.

Grants for Dental Teaching and Research

The Nuffield Foundation has agreed to make grants for the promotion of dental teaching and research in Great Britain. The assistance provided by the Foundation is to be in three parts. First, grants totalling £9,000 a year for ten years are to be made to the Sutherland Dental School, University of Durham; University of Leeds Dental School; the Turner Dental School, University of Manchester; and Guy's Hospital Dental School, for the development of research work on preventive dentistry. Secondly, Nuffield dental fellowships will be established to improve the supply of dental research workers and teachers. Lastly, a few scholarships to enable dental students of outstanding ability to receive a more thorough scientific training will be awarded. Fellowships will be open to three groups of candidates: those with dental qualifications, university graduates in medicine, and thirdly those holding a university science degree; the annual value will be between £400 and £800. Scholarships, providing tuition fees and a subsistence allowance not exceeding £200 a year, are intended for candidates who, in the opinion of their dental school, would profit by receiving, during their course of training, additional instruction in anatomy and physiology. Forms of application for fellowships and studentships may be obtained from the Secretary of the Nuffield Foundation, 12–13 Mecklenburgh Square, London, W.C.1.

Announcements

Mr. Archibald N. Black has been appointed Donald Pollock reader in engineering science in the University of Oxford.

Dr. J. E. Hurst, technical director of Bradley and Foster, Ltd., Bradleys Concrete, Ltd., of Darlaston, and director of research of the Staveley-Bradley, Foster Research Laboratory Institute at Sheepbridge, is to be Sheriff of the City and County of Lichfield. Dr. Hurst is president of the Staffordshire Iron and Steel Institute, and is known for his work on the heat treatment of cast-iron and the development of cast-iron suitable for nitrogen hardening.

The Stephen Paget Memorial Lecture of the Research Defence Society is being resumed this year and will be given by Sir William Savage on the occasion of the annual general meeting of the Society, the title being "Public Health and its Debt to Experimental Medical Research". The meeting will be held at Manson House, Royal Society of Tropical Medicine and Hygiene, London, on October 12.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Anti-*Hr* Sera

THIS communication is sent in order to acknowledge an error which has misled Race, McFarlane, Cappell[1] and Fisher[2] in their communications in *Nature* of May 5, 1945, entitled "Anti-*Hr* serum of Levine". At the same time, I take the occasion to make a few additional comments on some of the problems in this new field of research, so important for the clinician as well as the theoretical investigator.

In their discussion on the relationship of the anti-*Hr* and their *St* serum, the British workers conclude that these sera are not identical. On purely hypothetical considerations, Fisher had previously assumed the existence of at least three different varieties of anti-*Hr* sera, named by him, γ, δ and η. Until recently, the only anti-*Hr* sera described corresponded to the variety γ, which gives about 80 per cent positive reactions among white individuals. A serum of the type η characterized by an incidence of 96 per cent reactions was recently studied by Mourant[3].

Race and Fisher now believe that the one of the anti-*Hr* sera of Levine corresponds to the hypothetical antibody δ of Fisher. The only evidence in support of their contention is derived from the following statement made, but not further substantiated, in a paper by Waller and Levine[4]: ". . . in tests with a potent anti-*Hr* serum all the Rh_1Rh_2 bloods gave negative reactions . . .". Unfortunately, this statement does not correctly describe my actual findings, which were hitherto not published but were mentioned incidentally in the paper by Waller and Levine entitled "On the *Rh* and Other Blood Factors in Japanese".

In order to clarify the situation, the results of tests on the blood of 335 white and 135 coloured individuals with potent anti-Rh_0, anti-Rh', anti-Rh'', and anti-*Hr* are summarized below. The error mentioned occurred in the brief reference to these studies carried out during April–July, 1944.

Number tested	White (335)		Coloured (135)	
Type	Incidence	*Hr* positive (%)	Incidence	*Hr* positive (%)
Rh_1Rh_2	14·63	100	4·44	100
Rh_2	16·72	100	16·30	100
Rh_1	49·85	61·7	23 70	96·3
Rh_0	2·69	100	45·93	100
$Rh'Rh''$	0·00		0·00	
Rh''	1·19	100	0·74	100
Rh'	0·87	100	1·48	100
Rh negative	14 03	100	7·41	100
All types		80·9		99·3

Accordingly, the only statement which could be made is that all bloods of the type Rh_1Rh_2 tested are *Hr* positive. I freely admit an error which, although serious, must nevertheless be classified under the category of the clerical variety. It would never have been possible if the data given above had been published in tabular form.

Incidentally, the anti-Rh'' serum employed was derived from an Rh_1 patient immunized by repeated transfusions (titre about 1 : 40). In contrast to Wiener's anti-Rh'' serum, no other agglutinins were present. The anti-*Hr* serum briefly referred to elsewhere[5] had a titre of 1 : 100.

In accordance with Levine's definition of anti-*Hr* specificity, all bloods negative with anti-Rh' (*Rh* negative and Rh_2) give strong reactions with anti-*Hr* sera, while the remaining bloods Rh_1 and Rh' are either negative or give weak reactions[5,6,7]. When the first anti-*Hr* serum, of weak activity, was described in 1941, large quantities of potent human anti-Rh_0 and anti-Rh' sera were already available and distributed by me to several medical centres in the United States. (The first statistical study with these two sera were made by Levine and co-workers in the months of April to June, 1941. At the written request of Dr. Wiener, the incidence of the four subtypes and their reactions with anti-*Hr* serum were made available for the third edition of Dr. Wiener's book[8].) Anti-Rh'' sera were independently described two years later by Race *et al.*[9] and Wiener[10]. As shown by Race, anti-*Hr* agglutinins may now be more rigidly defined also in their relationship to anti-Rh'' serum. Thus, all bloods Rh_1Rh_2, $Rh'Rh''$, and Rh'' react with anti-*Hr* sera of the γ variety.

In the series indicated in the accompanying table, individuals negative for *Hr* were observed in only one type, Rh_1, and these, genetically Rh_1Rh_1, comprise 38·3 per cent of type Rh_1 of the white series. *Hr* negative individuals can be found also in the much smaller group of Rh'.

The incidence of *Hr* positive reactions in the entire white and coloured group were 80·9 and 99·3 per cent respectively. These figures compare well with Wiener's findings of 72 per cent and 98 per cent respectively[11]. As suspected by the latter, his anti-*Hr* serum was not sufficiently active and undoubtedly gave too many negative reactions.

The confusion with regard to the specificity of anti-*Hr* sera is due in part to the practical difficulty in collaboration on the part of British and American workers during the war years. Another factor was my failure to publish more fully on the properties of the potent anti-*Hr* serum referred to briefly in my several papers. A mere statement in the literature that my more potent anti-*Hr* serum gave about 80 per cent positive reactions would have enabled Race and Fisher to detect the clerical error quoted above.

Accordingly, there is no doubt that the *St* and *Hr* sera contain identical antibodies, corresponding to the variety γ of Fisher. This holds true for four sera in the collection of Race, at least two of the three sera observed by Levine, the *Hr* serum of Wiener, Davidsohn and Potter[11], and an extremely potent serum of Vogel. The discovery of η serum by Mourant seems to confirm Fisher's views, but a serum corresponding to the specificity of δ characterized by failure to react with Rh_1Rh_2 is still to be described.

The correlation of the studies by the American and British workers in this complex field is rendered difficult also because of several different terminologies. Another complicating factor is the uncertain supply and the lack of potent reagents essential for genetic investigations based on family and racial studies. This is particularly true for anti-Rh'' and anti-*Hr* sera (γ and η) especially with regard to the existence of several phenotypes of remarkably low incidence[12].

So far as the varying terminologies are concerned, it will undoubtedly become necessary for an international committee of geneticists and serologists to recommend a uniform terminology. Since isoimmunization by the factor *Rh* and its variants is important clinically, one can scarcely expect the clinician to commit to memory, at this stage, several different systems of terminology.

From the point of view of prevention of transfusion accidents and the diagnosis and treatment of erythroblastosis fœtalis, the clinician should concern himself exclusively with the anti-Rh_0 serum, the only one available to hospitals in the United States, and presumably also in Great Britain[13]. I have shown[5] that 92 per cent of all cases of isoimmunization by the *Rh* factor can be detected with this diagnostic reagent. Until a final genetic theory and uniform terminology are agreed upon, it is preferable for the clinician to think in terms of a simple genetic theory based on the behaviour of the standard diagnostic anti-Rh_0 serum which contains but a single antibody. For the exceptional 8 per cent *Rh* positive individuals immunized by variants of the *Rh-Hr* system or other blood factors, the clinician must consult the serological specialist, who may not have on hand potent anti-Rh'' or anti-*Hr* sera.

Effect of Tissue Extracts in controlling *Staphylococcus aureus* Infections

FOR a number of years our laboratories have been conducting investigations on natural cellular substances, some of which are stimulatory and some inhibitory to growth of tissues and micro-organisms[1,2,3,4]. In connexion with the work on bacteria, we recently reported a substance isolated from both human and ox spleens which, *in vitro*, was germicidal in concentration as low as 1 part in 2,000 for *Streptococcus hæmolyticus*[5]. The present investigations, conducted on *Staphylococcus aureus*, were undertaken as an extension of this work with spleen extract and also include observations on various other ox tissue extracts, primarily brain, heart and kidney.

With extracts of the aforementioned ox organs prepared in a manner similar to that mentioned in a previous report[5], a series of *in vitro* and *in vivo* experiments were conducted on 48-hour cultures of *S. aureus* incubated at 37·5° C. The *in vitro* experiments, incorporating 0·5 and 1·0 per cent of the extracts by weight in the media, indicated that after an initial three-day period of depressed growth, the organism was definitely stimulated, so that at the end of the sixth day colony size and number of the experimentals had increased 2·5 to five times that of the controls. Coincident with this increase in growth, there occurred a decided change in the morphology of the organism, the colony growth being converted from an original orange or yellow *S* variety to a white *R* configuration. Further study also indicated that these organisms varied from the controls in their biochemical characteristics (see table). Except for small percentages of difference in the amount of growth stimulation, these results were the same with all four of the tissue extracts tested.

Tests	Yellow *S* Control organism	White *R* Experimental organism
Fermentation of mannitol	+	−
Liquefaction of gelatin	+	+ (slight)
Chromogenesis	+ (yellow)	− (grey-white)
Hæmolysis	+	−
Coagulase reaction	+	−

Despite the fact that under the influence of the extracts the growth of *S. aureus* had been stimulated, it was felt that the change in biochemical characteristics of the organism following its conversion from the yellow *S* form to the white *R* might have been accompanied by a change in virulence and was therefore of sufficient importance to merit *in vivo* testing. These tests were divided into three separate experimental groups and conducted only with brain extract, since, *in vitro*, this extract had produced the most rapid conversion to the white *R* form. White mice were used in all the experiments, 20 being employed for each experimental group, 10 serving as controls and 10 as experimentals.

First experimental group. In this experiment, conducted for the purpose of determining whether *S. aureus* grown *in vitro* under the influence of brain extract retained its altered characteristics *in vivo*, control mice were infected subcutaneously with 1 c.c. of freshly prepared saline cultures of the yellow *S* organism, while experimentals were infected with a similar amount of the white *R* form. No tissue extract was injected into any of the animals. Three days after infection, control animals developed a gradually ascending paralysis, which resulted in 70 per cent mortality by the fourth day. The remaining 30 per cent developed large abdominal abscesses and sloughs which persisted for three weeks. On the other hand, there was no mortality among the experimental animals. These animals did not develop paralysis, and only 20 per cent developed abdominal lesions of a very minor character which disappeared by the seventh day. Cultures from the lesions in the two groups of animals revealed organisms corresponding to those injected, both as to colour and biochemical characteristics, thus indicating that the white *R* form retains its altered characteristics *in vivo* and as such is less virulent than the yellow *S* form.

Second experimental group. This experiment was conducted as a test of the prophylactic action of brain extract against *S. aureus* infections. Forty-eight hours prior to the subcutaneous inoculation of all animals with 1 c.c. of suspension of yellow *S* organisms, the experimental group was injected subcutaneously with 50 mgm. of brain extract, and thereafter at 24-hour intervals throughout the experiment. Three days after inoculation with staphylococci, all control animals had developed large abdominal abscesses which resulted in 50 per cent mortality. Those animals that lived required three weeks for complete healing. Of the experimental animals, 50 per cent developed no abscesses whatever. The remaining 50 per cent developed very small lesions which were healed in ten days. Total dosage of brain extract for each animal was 500 mgm.

Third experimental group. This experiment was conducted as a test of the therapeutic action of brain extract on *S. aureus* infections. All animals were infected in the manner described for the prophylactic experiment. When the animals developed abdominal lesions on the third day, they were divided into control and experimental groups, and the latter were given daily injections of 50 mgm. of brain extract. As early as two days after the injection of the brain extract, definite improvement was noted in the experimental animals, and by the fourteenth day of the experiment or the eleventh day of treatment all animals were completely healed. There was no mortality. The abscesses in the control group, however, continued to progress and resulted in a final mortality of 60 per cent and a delay in healing of the remaining 40 per cent of three weeks.

Conclusions. A factor has been extracted from ox brain, spleen, heart and kidney tissue, which *in vitro* is capable of converting yellow *S* forms of *S. aureus* to white *R*, the latter having biochemical characteristics quite different from the former. Moreover, this organism retains its altered morphological and biochemical characteristics *in vivo* and is definitely less virulent than the yellow *S* form. Prophylactic and therapeutic tests with the brain extract show that it is effective in preventing and treating *S. aureus* infections, the efficacy of the treatment probably resulting from a decrease in virulence of the organism produced as a result of alteration in its morphological and biochemical characteristics.

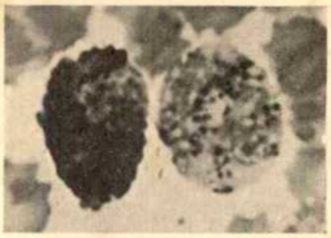
Differentiation between Eosinophils and Pseudo-eosinophils of Rabbits' Blood by means of a Peroxidase Reaction

THE difficulty of distinguishing between eosinophil and pseudo-eosinophil leucocytes in rabbits' blood stained with the usual blood stains is well known. Ehrlich's triglycerin mixture, in which the eosinophil granules are shown up specifically in yellow, gives irregular results and, in general, rather unsatisfactory smears. Recently, I described a new technique for the peroxidase reaction on leucocytes in human blood films employing 2,6-dichlorphenol-indophenol[1]. This technique applied to films of rabbits' blood allows the observer easily to single out the eosinophil leucocytes, even under relatively low power (for example, × 200).

The most suitable procedure is to treat for 5–10 min. fresh, air-dried, formol-alcohol fixed blood films with a mixture of 0·05 per cent aqueous solution of 2,6-dichlorphenol-indophenol (4 pt.) and 0·5 per cent solution of neutral red (1 pt.), to every 5 c.c. of which four drops of hydrogen peroxide (4 vol. per cent) had been added prior to use. After a short wash, the film is blotted dry and oil is directly applied. Under these conditions the cytoplasm of the eosinophil leucocytes is densely packed with heavily stained large spherical granules (up to 1·5 μ in diameter); almost every granule shows a dark purplish-black periphery and a somewhat lighter interior, the colour of which ranges between mauve and a dirty greyish blue, while the pseudo-eosinophil granular leucocytes show much smaller (about 0·5 μ) and scattered dark purplish granules, some of which are more ovoid or rod-shaped than spherical; the granules vary in size, and some, if big enough, also appear as dark rings with a tiny light centre. The contrast between the two types of cells is particularly striking after a short reaction time when only a limited number of granules in each pseudo-eosinophil is stained. If the time is prolonged to 20 min. or more, many more granules in each pseudo-eosinophil become positive This observation is opposed to the view that the enzyme is situated actually on or in the granules.



TWO GRANULAR LEUCOCYTES OF RABBITS' BLOOD; EOSINOPHIL ON THE LEFT. × 1600.

Measurements of cell diameters made with these preparations show the eosinophils to vary from 10 to 12 μ, and the other granular leucocytes from 7 to 10·5 μ. In differential counts the eosinophils are found to represent 1 per cent or less of the white blood corpuscles, which figure agrees well with Klieneberger's data[2]. The relative number of basophils has to be determined by means of one of the usual blood stains.

Cosmic Radiation Observed at the Col du Lautaret, Hautes-Alpes

LES deux clichés reproduits ici ont été pris dans l'été 1943 au col du Lautaret (2,060 m.) au cours d'une mission organisée par M. Leprince-Ringuet La détente de la chambre de Wilson était commandée par trois compteurs dispersés sur une aire d'une dizaine de m.[2]; deux de ces compteurs étaient couverts de 4 ou de 8 cm. de plomb. Les gerbes des figs 1 et 2 sont donc secondaires de grandes gerbes d'Auger particulièrement riches en rayonnement pénétrant.

La gerbe de la fig. 1 est issue de 14 mm. de laiton Elle est essentiellement constituée de cinq paires serrées régulièrement disposées et faisant entre elles un angle d'environ 1/10 de radian. Les premières deux paires sont visibles sur les images latérales, les trois autres malheureusement pas.

La gerbe comprend une particule lourde (meson ou proton) arrêtée dans l'écran de 15 mm. de plomb Les deux trajectoires de la première paire paraissent donner un secondaire : la première traverse ou donne un secondaire peu dévié (5°) ; la deuxième donne un

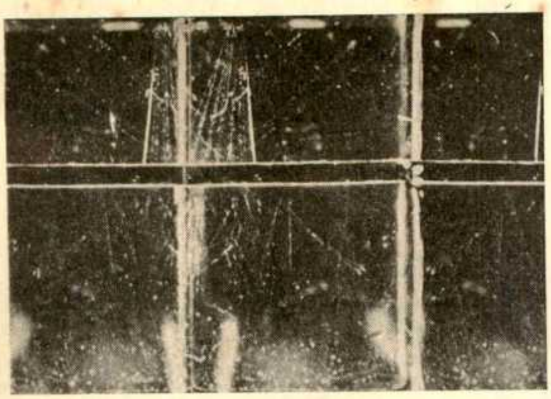

FIG. 1.

secondaire très divergent ou subit une très forte diffusion. Les deuxième et troisième paires sont bloquées. La quatrième paire comprend sans doute en réalité trois trajectoires. L'une d'entre elles est gerbigène et probablement une autre traverse. La cinquième paire donne naissance dans le gaz à un secondaire de grande énergie.

La gerbe de la fig. 2 est créée dans l'écran de 15 mm. de plomb. Elle comprend trois paires faisant un angle de 5° entre elles. Les deux paires latérales sont décomposables à l'observation stéréoscopique. La trajectoire centrale d'ionisation identique ne peut être celle d'une particule lourde lente, un électron de choc de plus de 10 cm. de parcours ne peut avoir été éjecté que par une particule de plus grand v/c que 0·7 et d'ionisation inférieure à 1·5 fois le minimum. Cette trajectoire médiane résulte donc de la superposition de deux trajectoires rapides.

Il existe dans cette série de clichés deux autres gerbes de paires moins typiques et plus discutables.

La diffusion élastique multiple est d'après Euler, Molière, Landau, Bethe, Williams, l'effet prépondérant dans les gerbes cascades. Elle ne peut donner lieu à ces figures régulières et planes. Ces gerbes sont des gerbes de type Heisenberg où plusieurs particules sont créées en un seul acte. Elles paraissent polarisées et semblent impliquer une interaction de spin. La présence d'une particule lourde et probablement d'une ou deux particules pénétrantes semble d'ailleurs suggérer que le champ perturbateur est un champ du type nucléaire comme le prévoit Heisenberg. Elles paraissent associées aux gerbes d'Auger.

Lorsque de telles gerbes se produisent à une profondeur notable dans les écrans, leur régularité géométrique disparaît forcément par absorption, déviation et multiplication des trajectoires.

Packing of Regular (Spherical) and Irregular Particles

RECENT correspondence[1,2] in *Nature* cites a theorem on the ordered packing of equal spheres to prove that packings of graded sizes of coal have the same voidage (fraction of free space) for all sizes. This theorem can be stated in its most general form as follows: the overall voidage of any one of the four possible ordered arrangements of equal spheres packed into a container is independent of the relative size of the container provided its size and shape are such that it will contain an integral number of 'unit' cells of the particular ordered arrangement; in all other cases an ordered packing cannot be obtained. Graton and Fraser[3] have given the size and shape of the 'unit' cells for the four arrangements, where one sphere touches six (cubic), eight (orthorhombic), ten (tetragonal) and twelve (rhombohedral) neighbours respectively. The same authors give the correct voidages 0·4764, 0·3954, 0·3019 and 0·2595 for the four cases and discuss also the case of ordered packings of spheres of different sizes. (Mr. Ackermann's figures for the case of eight contacts on each sphere appear to be incorrect.)

This theorem does not apply to the packing of coal for two reasons. First, equal spheres poured into a box take up a disordered arrangement[4], with a voidage between 0·45 and 0·37. Secondly, irregularly shaped particles pack in an entirely different manner. Although the packing is still disordered, the frequency distribution of numbers of contacts are different, particularly for the looser packings. (Compare Smith, Foote and Busang's tests[4] on lead shot, and Bennett and Brown's tests[5] on starch particles.)

It is possible that the observed constant voidage of irregular materials of different sizes is due to two opposing effects. Spiers[6] quotes voidages for packings of graded coal lumps ranging from 0·47 to 0·54 as the size decreases from 1 in. × $\frac{1}{2}$ in. to $\frac{1}{8}$ in. × $\frac{1}{16}$ in. We have found the opposite effect in a small container (10 in. cube); here the voidage decreases from 0·47 to 0·43 for coal sizes from 1 in. × $\frac{1}{2}$ in. to $\frac{1}{4}$ in. × $\frac{1}{8}$ in. Thus an apparent independence of size might be found in practice with certain materials and sizes of containers. Generally, the voidage increases as the relative size of container to particle decreases.

In conclusion we should like to direct attention to Osborne Reynolds' principle of dilatancy[7], which has been overlooked by almost all workers in the field of packing of granular materials. We have shown recently that the principle of dilatancy accounts not only for the non-uniformity in the transmission of forces through granular beds observed and discussed by Jenkin[8], but also for gross non-uniformities in the distribution of local voidage which we have found[9] to be inherent in packed materials (see figures). In practical applications, in fuel beds and coal treatment processes, for example, the non-uniformity of the packing is likely to be of greater significance than any average property such as the overall voidage. For this reason at least, apart from the reasons mentioned above, studies of the geometry of

Measurement of High Voltages

ABSOLUTE measurements of high voltages, up to about 300 kilovolts, have been carried out by various workers using instruments of the attracted disk type, as originally devised by Lord Kelvin, in which the electrostatic deflecting force on the disk is balanced by mechanical means. When such instruments are operated in air, large spacings are necessary for the higher voltages, and difficulties arise in the production of a uniform field without the use of excessively large electrode diameters. This has been overcome to some extent by one group of workers[1], who have enclosed the cylindrical space between the electrodes with a series of guard-rings. In another arrangement[2], the apparatus is operated in compressed gas, with a consequent reduction in the spacing between the electrodes for a given voltage.

It has occurred to us that there are considerable advantages to be obtained by the enclosure in vacuum of the attracted disk electrometer, and of other forms of electrostatic voltmeters. The working voltage gradient for instruments operating in air is limited to a value below about 10 kV. per cm., whereas, in vacuum, a voltage gradient of more than 100 kV. per cm. can be used. For a given voltage, therefore, the spacing between the electrodes in vacuum can be reduced to less than one tenth of that in air, so that the production of a uniform field between the electrodes can be simplified and a more compact form of instrument can be made. As the attractive force between the electrodes varies as the square of the voltage gradient, a greater mechanical precision is possible for the vacuum-enclosed instrument; an attractive force of 4·5 gm. per cm.^{2} of electrode area may be obtained in vacuum for a gradient of 100 kilovolts per cm.^{2} as compared with 0·045 gm. per cm.^{2} at 10 kilovolts per cm.^{2} in air.

An attracted disk electrometer enclosed in a continuously evacuated system is now being constructed, and will be used for the absolute measurement of both A.C. and D.C. high voltages. Little difficulty is anticipated in obtaining an accuracy of within 0·3 per cent in the measurement of voltages of 100 kilovolts or more.

On account of the large deflecting force available, the instrument can be made of more robust construction than one operating in air, and an improved accuracy and greater reliability of indication can be obtained. There is an absence of convection currents, which is one of the causes of difficulties in the operation of the air type of instrument. Also there is freedom from interference by dust and humidity.

Similar advantages to those claimed above for the attracted-disk electrometer are obtained in direct-reading electrostatic voltmeters when these are enclosed in vacuum. Several of these instruments are being developed, for various voltage ranges, extending from several kilovolts to hundreds of kilovolts. One such instrument has already given satisfactory operation in the measurement of voltages between 50 and 100 kilovolts. Although continuous evacuation is used in the present designs, it is intended later to seal the mechanism in a glass-metal envelope.

Further information concerning these developments will be published in due course.

We express our appreciation to Sir Arthur P. M. Fleming, director of research and education, Metropolitan-Vickers Electrical Co., Ltd., for permission to publish this note.

Anodic Deposit of Protactinium

PREVIOUSLY described experiments[1] have shown that under certain conditions of electrolysis of sulphuric or hydrofluoric solutions of protactinium, this element can be deposited on the cathode, at least in extremely thin layers. I have now observed, in sulphuric solutions, an anodic deposit on a lead oxide (PbO_2) support. Normal solutions of sulphuric acid containing about 10^{-5} gm. of protactinium in presence of 1 or 2 mgm. of zirconium sulphate were used. With a cathode of platinum, an anode of platinum covered with lead oxide (PbO_2) and a current of 5–20 mA./cm.^{2}, the yield is 30–60 per cent after two or three hours, with moderate stirring. Under these conditions the deposit on the cathode is insignificant. An anodic deposit can also be observed on gold anodes, but these electrodes are severely attacked. I have never observed an anodic deposit on pure platinum electrodes. The yield is reduced if sulphuric acid is replaced by nitric acid.

The influence of the nature of the anode is not due to a difference in oxygen overvoltage. Measurements of the potential of the three types of electrodes against a calomel electrode were carried out and have shown, for a given current density, no significant difference; if anything, electrodes covered with lead oxide show a smaller positive potential than the platinum and gold ones. It is known, however, that PbO_2 anodes favour electrolytical oxidations; for example, the formation of chromic and periodic acid.

As to the nature of the deposit, it is still uncertain. Usually, metallic peroxides formed at the anode correspond to a state of valency of the metal superior to the normal. The valency of protactinium in sulphuric solutions being already 5, what can be the valency of the anodic peroxide?

The investigation is being continued in order to clear up this question, as well as the mechanism of the deposition.

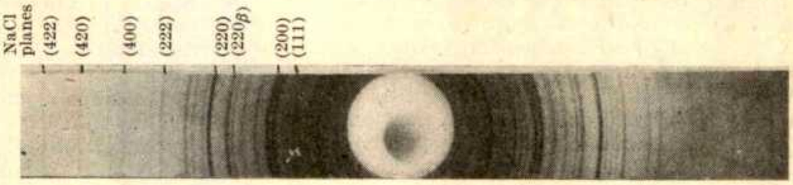
X-Ray Study of the Solution of Alkali Halides in Borax and B_2O_3 Glass Systems

A NUMBER of salts including alkali halides dissolve readily in glass. It has been suggested by S. K. Majumdar and R. M. Palit[1] that an X-ray investigation of the nature of these salts in the dissolved state inside the glass medium would be interesting. Such a study is naturally expected to give information regarding whether these salts form ionic, molecular or colloidal solutions, combine chemically with the glass medium, or induce any crystallinity in the glass itself. An investigation in these directions is being carried out in this laboratory.

Powder photographs of various alkali halides dissolved in glassy B_2O_3 and borax were taken at different concentrations and compared with powder photographs of the crystals of these substances. In the case of sodium chloride dissolved in borax, all the lines of sodium chloride and some lines which belonged neither to it nor to any of the known crystalline sodium borates appeared, as shown in the accompanying reproduction. The positions and relative intensities of the sodium chloride lines were identical with those of the pure salt. The sharpness of these lines indicates that *crystallites* of sodium chloride enter into glass. The average size of the particles in these colloidal solutions is under investigation. The only effect of using different concentrations of sodium chloride in borax was that the intensities of the sodium chloride lines increase with concentration. In the case of sodium chloride dissolved in B_2O_3 glass, the results were similar except that the new unidentified lines appeared only in weak solutions. For potassium chloride dissolved in borax and B_2O_3, the results were again similar; while in the case of rubidium chloride only the lines of pure rubidium chloride were obtained.



Thus we find that the alkali halides form colloidal solution in glass; the particle sizes are sufficiently large as to give sharp reflexions. Determination of the average size of these crystallites by measuring the half-intensity widths of these lines is in progress. Attempts are also being made to trace the origin of the extra lines that have been observed in the cases of dissolved sodium chloride and potassium chloride.

Two of us (S. K. M. and B. K. B.) are grateful to the Board of Scientific and Industrial Research of the Government of India for financial help.

Harmonics in the Piezo-Electric Oscillation of a Quartz Crystal

S. Parthasarathy, A. Pande and M. Pancholy[1] have recently given evidence of oscillation of the quartz crystal not only at odd harmonics but also at even and half-odd harmonics. In the third column of Table 1 in their communication, there are fourteen values of the ratio of the frequency to the fundamental which they got from a single quartz plate: 0·499, 1·00, 1·465, 1·96, 2·69, 3·00, 3·50, 4·00, 4·40, 5·00, 5·35, 6·23, 7·04, and 8·00.

In the course of an experiment on supersonic waves propagated in liquid, we have also noticed the harmonics produced by the piezo-electric oscillation of a quartz crystal on the background of a continuous range of frequencies of oscillation. The electric circuit we used was an ordinary Hartley type with an output of about 6 watts only. Eleven quartz plates, of different shapes, circular, rectangular and square, were used. They were cut and ground in this Institute, except one which was given to us in exchange by the American Air Force in Kunming. They were either *AT*-cut or *X*-cut, and no thickness variation on each plate more than 0·005 mm. was observed.

The quartz plate was clamped on a holder immersed in distilled water. A hot-cathode sodium discharge lamp of 40 watts was used as light source. The diffraction pattern was observed with a reading telescope of focal length 247 mm. The frequency of oscillation was measured with a G. E. wave-meter of precision type.

As soon as the electric circuit began to oscillate, the diffraction pattern appeared; as the frequency of the electric circuit increased by turning the condenser in the tank circuit, the spacing between the diffraction lines was gradually and continuously widened. The diffraction pattern usually gave one or two orders. However, at certain particular frequencies, the milliammeter in the plate circuit recorded a sudden jump; at the same time the diffraction pattern went up to a higher order and its intensity abruptly increased. For example, one of eleven quartz plates was a circular disk of 18 mm. in diameter and 1·337 mm. in thickness. It was *X*-cut, and its fundamental frequency measured 2,080 kc. It was then submitted to the electric circuit for oscillation. From 2,000 to 14,000 kc. there were twelve frequencies where the jumps on the milliammeter occurred and the order and intensity of the diffraction pattern increased. The exact values of the ratio of the frequency to the fundamental were found to be 1·00, 1·72, 1·94, 2·04, 2·16, 2·65, 3·00, 3·13, 4·00, 4·45, 5·00, 6·20. They were believed to be closely, if not exactly, the odd, even and half-odd harmonics which Parthasarathy and his collaborators found. Throughout the whole range of oscillation, the diffraction patterns never failed to appear, although at certain places they were barely visible even with the help of a telescope.

It will be remembered that the Hartley circuit has a strong feed-back, so the crystal is forced to vibrate. It seems that the quartz crystal can be forced to vibrate over a wide range of frequency as soon as its impedance has been overcome, and that it particularly shows the resonance of vibration at the frequencies of $\frac{p+1}{2}f$, where f is the fundamental frequency of the quartz crystal and p is an integer. The odd harmonics oscillate much more strongly than the even, as is indicated by the intensity and number of orders of the diffraction pattern. If we put the crystal in a Pierce circuit which has a weak feed-back and is generally regarded as less active in oscillation, the crystal only oscillates at its fundamental frequency and odd harmonics. It may be added that in the forced vibration, the harmonic vibrations do not come out very exactly, and they may change their resonance frequencies when a different mode of excitation, as in different conditions of clamping the crystal, is used.

Hexachlorocyclohexane as an Insecticide

My attention has been directed to the possibility that Dr. L. B. Bourne's letter[1] may be read as implying that Dr. E. L. Taylor's reference[2] to hexachlorocyclohexane, supplied by Imperial Chemical Industries, as a "new" insecticide was unjustified in the light of recent information that this material has been available as an insecticide in France for some years.

I am asked to emphasize that it was in the spring of 1943 that I.C.I. made the important and unexpected discovery that the remarkable insecticidal properties of hexachlorocyclohexane are almost entirely associated with only one of the four isomers (gamma) which had first been isolated thirty-one years earlier. The Company, however, was not permitted by the Government to disclose this or the extent to which hexachlorocyclohexane had been manufactured and used as an insecticide in Britain until 1945, when an announcement was made in the Hurter Memorial Lecture (not yet published) to the Society of Chemical Industry on March 8. This discovery of the outstanding insecticidal activity of 'Gammexane', as the gamma isomer has been called, made possible a planned development of hexachlorocyclohexane as an insecticide.

Thus sufficient material was produced to meet the 1943 demands of agriculture for a dust to replace derris, then in short supply, for the control of flea beetle. The material proved so successful, not only in the control of many agricultural and horticultural pests, but also in trials against locusts and industrial pests such as cockroaches, crickets, bed bugs, flies, etc., that production was increased in the following two years and the material was made available for these widely varied applications. Up to the time when the Government permitted the disclosure of the nature of the active constituent of the material, hexachlorocyclohexane equivalent to several thousand tons of insecticidal dust had been produced in Britain.

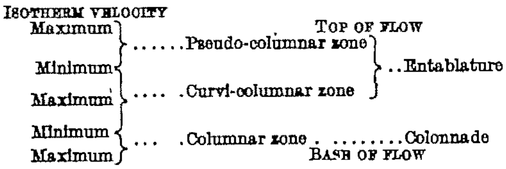
THE GIANT'S CAUSEWAY

"SURE, an' if ould Finn did not build it, how did it come to be there, at all?" Although the world-famous Causeway—justly claimed by Molyneux in 1694 to be "as Remarkable a Natural Curiosity . . . as may be met with in Europe"—has long offered a challenge to geologists, there has hitherto been no satisfactory account of its petrology, structure and geological setting. This singular neglect of a classic area stimulated S. I. Tomkeieff to make a thorough investigation of the basalt lavas of the Causeway and its environment, and just before the War he communicated his results to the Association de Volcanologie in a masterly paper[1] which was printed in Naples in 1940. Fortunately, this eagerly awaited publication has survived, and copies are now available in Britain.

In Antrim a lower series of lavas (olivine-basalts) is normally separated from an upper series (columnar tholeiitic basalts) by a major interbasaltic (lateritic) zone. The sequence is magnificently displayed in the cliffs adjoining the Causeway. The Causeway itself is a terrace carved by the sea from the lowest of the tholeiitic flows, the base of which, to be seen only at very low tide, has been found by Mr. Tomkeieff resting directly on fresh olivine-basalt belonging to the lower series. On each side of the Causeway, however, the columns rest on the interbasaltic zone at a height of about 70 ft. above sea-level. The basalt flow of the Causeway is therefore regarded as having filled a river valley excavated through the interbasaltic zone into the underlying olivine-basalts. The divergent arrangement of the columns, at right angles to the valley sides, fully accords with this simple interpretation of the apparently anomalous position of the flow where it forms the Causeway.

In vertical section, columnar lavas of the Causeway type have a conspicuous two-fold arrangement for which a new terminology is proposed. The lower zone of vertical polygonal columns is referred to as the 'colonnade', while the upper zone of less regular jointing is distinguished as the 'entablature'. The latter is subdivided in turn into a lower 'curvi-columnar' zone (thin, curving columns, often radiating from marginal points) and an upper *pseudo-columnar* zone (thick, short polygonal blocks) which is usually surmounted by a thin slaggy and vesicular zone. The different joint systems responsible for these structural zones are most ingeniously explained by Mr. Tomkeieff as consequences of the varying velocity of propagation of isotherms during the cooling history of a flow. From the calculated distribution of temperature in a cooling sheet, curves are drawn indicating the temperature reached at different levels at the ends of successive and equal time intervals, and from these curves others are derived showing the velocity of the inward progress of the isotherms. The velocity-of-propagation curves show three maxima (one at each margin and one in the middle) with two minima between. The latter divide the sheet into three parts which are correlated with the three sets of structures seen in each flow. The rate of advance of the critical isotherm corresponding to the fracture-point determines the nature of the jointing, while the amount of the accumulated stress determines its magnitude. The free surface and the high initial velocity of the isotherms at the top controls the widely spaced, crude jointing of the pseudo-columnar zone, while the absence of a free surface at the base and the smaller initial velocity of the isotherms gives rise to the more closely spaced joints of the colonnade. Between the two minima, each of which corresponds to a pause in the fracture process, an unfractured zone remains sandwiched for a time. Eventually the final rapid increase of isotherm velocity, and therefore of stress accumulation, promotes an increased tensile strength (on analogy with the behaviour of glass rods), and so leads to overstraining which culminates in the violent fracturing represented by the tangle of wavy joints characteristic of the curvi-columnar zone.



After the formation of the columnar fissures, escape of gases from the cooling lava would be greatly facilitated, and as expanding gases are a most efficient cooling agent, the temperature of the margins of the columns would rapidly fall. Contraction of the outer part of a column would throw it into compression, while tension would gradually develop in the inner part. A cross-rupture would originate at the point of maximum tension somewhere inside the column and would spread rapidly round and then inwards and outwards, giving rise to a curved joint representing the first stage in the formation of a transverse 'ball-and-socket' joint. Minute variations in the delicate interplay of the principal stresses would determine whether a given joint curved upwards or downwards. Occasionally a fracture originating some way from the centre would fail to reach the centre, so bringing about the formation of a central knob, a feature that has long defied explanation. The outward progress of the curved fracture would normally stop along the circular line of no stress, to be completed by later fracturing as a horizontal lip. Sometimes, however, the original fracture would overshoot this limit and spread evenly to the margin. Both the central knobs and, generally, the outer lips have a granular fracture of later origin than the glossy fracture of the initial, curved joints.

It is pointed out that freshly opened joints in the tholeiitic lavas show glossy surfaces, with parabolic, radiating or feathery markings, which closely resemble fracture surfaces in glass. This similarity, the fine-grained and uniform texture of the rock, and the presence of interstitial palagonite and glass, all suggest that the fissuring took place while the lava was still in a semi-glassy or even glassy state. On the other hand, the olivine-basalts were probably crystallized completely before fissuring. Their joint-planes have a granular surface and the rock is of much coarser grain and lacks a glassy mesostasis.

Former petrographic descriptions of the Causeway basalt and its associates have been no more than brief notes. Mr. Tomkeieff now gives us a detailed account, including the mineralogy, modal composition and granularity of the flows above and below the major interbasaltic zone, together with new chemical analyses of the colonnade and entablature of the second of the upper flows. A good analysis of the Causeway basalt itself has been available since 1936 [2]. Other topics dealt with include the origin and mode of eruption of the lavas. The suggestion that the Antrim lavas belong to a multiple-vent type of shield-complex is favoured, in agreement with the recent conclusion of the Geological Survey that the lavas of the British Tertiary province were not necessarily erupted, as previously thought, through dyke-fissures.

Finally, it should be recorded that the history of 250 years investigation is most entertainingly summarized and fully documented. By his outstanding success in grappling with a group of problems that has tantalized many generations of "Inquisitive Naturalists", Mr. Tomkeieff has far outdistanced his predecessors. He is to be congratulated on a contribution which, for the first time in the history of the Causeway, may be hailed as thoroughly worthy of its impressive subject. ARTHUR HOLMES.

THE FILM IN SCIENCE

A CONFERENCE on "The Film in Science", organized by the Scientific Film Association, was opened at the Technical College, Huddersfield, on August 31, after a civic reception by the Mayor, Alderman Sidney Kaye; over 100 were present.

Mr. Geoffrey Bell (deputizing for Mr. Arthur Elton, president of the Association, who was in Denmark) said that the conference gave an opportunity for many different users of scientific films to state their needs and problems. That the Conference was held in the provinces implemented the Association's aim to be fully representative of Britain rather than metropolitan in character. The Scientific Film Association could bring to a focus the growing scientific culture partly represented by scientific film societies all over Britain—and also shown, significantly, by the chance that the B.B.C. on the following Sunday was broadcasting its first review of scientific films. He added that the pressure of events has now made it clear that a widespread understanding of what science stands for, long recognized as desirable, is a matter of the most vital necessity; and films can help to bring about this understanding.

Miss Dorothy Grayson (educational representative of the British Film Institute), speaking on "The Science Film in Education", said that one of the duties of science is to protect people from making blind assumptions. Films should fall into three categories: those which deal with the established sciences; those presenting the facts as known, with some attempt to derive conclusions from them; and those which give education in doctrines and values. "We always pretend," said Miss Grayson, "that schooling contains no element of propaganda, but we should be wiser if we faced the realization that it does. We try to pretend that we as teachers deal only with the facts, and that our own personalities and convictions never seep through. This is not true. The children do get their values very largely from environment, but these also come from the deliberate purposive education given in schools. Instruction and practice in critical deduction is very necessary." In school the film is especially valuable as a tool of exposition. The screen can bring into juxtaposition events separated in time and space, it benefits research inquiry by adjusting time- and sight-scales, and it makes history a living thing. The films also present the teachers' factual material in ampler form and leave them free to concentrate on interpretation. There should be abolition of customs duties on all educational films which merit international circulation, and a subsidy for the development of such work is also badly needed.

On the morning of September 1, Mr. W. F. Andrews (head of the Department of Chemistry, Physics and Biology, Doncaster Technical College), speaking on "Scientific Film Needs in Technical Training", said that from many years of experience he realized the need for three types of film covering the requirements of primary, secondary and advanced technical training. Mr. H. Richmond (head of the Mining Department, Doncaster Technical College) described the "Film Strip in Technical Training", emphasizing its value for revision purposes. He showed a strip which has been used as an introductory aid for acclimatizing mining trainees to pit work. Both speakers stressed the need for an immediate supply of such visual material, the value of which was demonstrated during the War in technical training for the Services.

In the afternoon, the use of the "Film as an Instrument of Scientific Research" was described and demonstrated by Mr. Derek Stewart (Kodak Research Laboratories). After a short historical account of the technical development of cinematography, he dwelt at some length on the various ways in which the modern camera has been perfected for specialized purposes. High speed enables as many as 3,000 exposures per second to be taken. Reductions in apparent speed of up to 200 to 1 are therefore obtainable when projecting such pictures at the normal rate. This technique has made valuable contributions to the analysis of motion of rapidly moving machinery and to the study of the mechanism of explosions. At the other end of the scale, time-lapse photography, used to such fine purpose by the late Percy Smith, has served to speed up the apparent rate of motion of slow-moving processes. Biological growths, for example, taking many months in real life, can thereby be presented visually and as a homogeneous whole in the space of a few minutes.

In the evening, Mr. Basil Wright (producer at the Crown Film Unit) talked on "Film Production". He emphasized that the new art of the film is only possible through the co-operation of many workers skilled in different spheres. Even if the exceptional man did all his own scripting, directing and cutting, he would be almost certain to have his processing done commercially. In the professional field, this means that film-making demands highly developed team-work. One aspect of this is the relationship between director and producer, best explained perhaps by saying that the producer has to see the wood while the director looks for the trees. In subsequent discussion, the need for instruction in film-making was emphasized. Medical men and scientific men would thereby be enabled to produce film records valuable as a means of exchanging ideas and imparting information. The existence at the University College, Exeter, of the first Visual Education Centre in Britain is a significant step towards academic recognition.

There followed a reading, in his absence, of a paper by Mr. Frank Goodliffe (director of Science Films) on the making of that most valuable part of the scientific film, the animated diagram. This was illustrated by the screening of one of his films.

On September 2, under the chairmanship of Surgeon Lieut.-Cmdr. R. C. MacKeith (chairman of the Medical Committee of the Scientific Film Association), there was a discussion on "The Film in Medicine", together with a show of films on public health and of specialized films for medical men and medical students. The need for presenting each subject from many different angles and in the light of opposing schools of thought was stressed by a delegate from South Wales, supported by many others. After seeing the film "Defeat Tuberculosis", he said that, admirable though it was in showing the cure of the disease under ideal clinical conditions, it might nevertheless lull the public, to whom it was designed to be shown, into a false sense of security. Apart from allaying the fear of 'T.B.' in the public mind, it should also have emphasized the urgent necessity for providing the ideal facilities to all who may be in need of them.

The value of the film in teaching medicine, and in particular, surgery, was demonstrated by a professionally made film on "Transplantation of Cornea Autokeratoplasty", as well as by an amateur production by three medical men from the Westminster Hospital on an "Introduction to Acute Inflammation".

Dr. W. T. Astbury (director of the Textile Physics Laboratory, University of Leeds) gave a lecture on 'X-Ray Adventures among the Proteins and other "Molecular Giants" on September 2. In this talk, garnished with a pleasant humour and illustrated by slides and 'working' models of proteins and fibre molecules, Dr. Astbury emphasized his conviction that the mere imparting of knowledge is not enough. Films should be made which show the quest for ultimate knowledge to be a dramatic and exciting adventure.

During the Conference, delegates inspected an exhibition of projectors and other visual aid equipment; spare projectors were kept busy running amateur-made films, and film strips. The scientific ilm review, broadcast in the Sunday evening "Science Magazine", interested many. Discussions followed all the lectures, and the Conference ended with a long programme of scientific films.

The Scientific Film Association will publish a full account of the proceedings as soon as possible.

TYROGLYPHID MITES AND HUMAN DISEASE

STUDENTS of applied zoology are familiar with the damage caused by Tyroglyphid mites to stored products valuable to man. The part they may play in the causation of disease is less well known.

Sir Philip Manson-Bahr and W. J. Muggleton (*Lancet*, 81, Jan. 20, 1945) direct attention to the ossible significance of mites and their eggs in human fæces. Invasion of the human alimentary, urinary nd respiratory tracts by tyroglyphid—and sometimes also by tarsonemid—mites has been reported y M. Khalil (*Proc. Roy. Soc., Med.*, 14, Sect. Trop. Dis., 24; 1921), who found the eggs of *Aleurobius farinæ* in 8 per cent of 130 Cornish miners; by J. Mackenzie (*J. Roy. Army Med. Corps*, 39, 339; 1922), ho found *A. farinæ* and *Tarsonemus* in recruits suffering from nocturnal enuresis and in one suffering om hæmaturia; and by others who found various mites in human sputum. The evidence about the possible effects of mites in the human alimentary canal has been reviewed up to 1929 by A. Hase (*Z. Parasitenkunde*, 1, 765; 1929). Some experts think that such common mites as *Glyciphagus domesticus*, *Aleurobius farinæ* (in meal) and the cheese mites *Tyroglyphus siro* and *T. longior* can be pathogenic if great numbers are eaten; others deny this. The dermatitis suffered by people who handle mite-infested foodstuffs (Grocer's itch, copra itch) is, however, well known (see *Lancet*, 351, Sept. 9, 1944). Manson-Bahr has seen dead mites in human fæces from time to time, and during the past year has been finding them with increasing frequency. Recently, eggs showing development from the morula stage to the newly hatched nymph have been found in the fæces of two patients. The mites could not be identified with certainty, but were probably *Tyroglyphus siro*. One of the patients had had recurrent diarrhœa and had come from the Isle of Man, where he had eaten much over-ripe cheese. Search for similar mites in the rationed cheese now being sold in Britain has failed. Manson-Bahr and Muggleton conclude that, so far as can be ascertained at present, the presence of mite eggs in human fæces has no pathological significance.

The possible effects of mites upon the respiratory tract are the subject of a paper by E. Soysa and M. D. S. Jayawardena (*Brit. Med. J.*, 1, Jan. 6, 1945) on pulmonary acariasis. During 1943–44 these authors observed a remarkably heavy incidence of bronchial asthma among patients in a hospital of the South-East Asia Command. From January 1942 until June 1944 bronchial asthma was responsible for 48 per cent of all respiratory cases and for 21 per cent of cases invalided out of the Army through this hospital. Some patients showed a high eosinophilia, which in asthma may be, according to Osler, as high as 53 per cent. But the patients rarely gave a family history of asthma or of other allergic symptoms; their eosinophilia was not due to intestinal parasites; drugs commonly given to relieve asthma gave only temporary relief to these patients, and their eosinophilia persisted. Major T. R. Jansen referred the authors to a civilian patient who had asthma with high eosinophilia, and mites were found in his sputum; he made a remarkable recovery after administration of pentavalent arsenic. Referring to the work in Ceylon of H. F. Carter, G. Wedd and V. St. E. D'Abrera (*Ind. Med. Gaz.*, 79, 163; 1944), who recovered species of *Tyroglyphus*, *Tarsonemus*, *Carpoglyphus*, *Glyciphagus* and *Cheyletus*, all common in stored products, dust, debris, etc., from 17 out of 28 patients, and found that arsenical treatment reduced both the numbers of the mites and the eosinophilia, Soysa and Jayawardena record their own observations.

The whole problem and its relevant literature is discussed by Soysa and Jayawardena, who found, as others have done, that treatment with arsenical preparations (they used 'carbasone' or 'stovarsol') was satisfactory. While the existing evidence does leave some doubt whether mites can alone cause all the asthma-like symptoms described, the problem requires further investigation. The differential diagnosis between this asthma-like condition and tuberculosis and other obscure and transient respiratory conditions with asthma-like symptoms and eosinophilia (for example, Loeffler's syndrome) may be especially difficult.

That monkeys of the genus *Macacus* suffer from pulmonary lesions in which mites are found is shown by L. J. Davis (*Brit. Med. J.*, 482, April 7, 1945), who quotes F. D. Weidman (*J. Parasit.*, 2, 37; 1915) on the acarids which he found in the lungs of *Macacus rhesus*. Davis found in the lung lesions of a species of *Macacus* (the species is not stated) mites which probably belonged to the genus *Pneumonyssus*, and he suggests that these mites may be normal ectoparasites of these monkeys, so that monkeys could readily inhale these mites. Experimental infestation of monkeys with them might, he suggests, help us to understand the problem of infestation of the human lung with mites. Davis says that the lesions in the monkey's lung resembled, to the naked eye, the lesions of early tuberculosis. This recalls the similar resemblance to tuberculous lesions of the lesions of organs other than the lung, for example, those of the mesenteric glands, caused by larvæ of the degenerate Arachnid *Linguatula*. But there is much histological evidence that lesions caused by parasitic nematodes (for example, various Filarioid species) may also resemble those due to tuberculosis. It is clear that the solution of this whole problem will require all the skill of the clinician, the pathologist and the biologist.

G. LAPAGE.

FORTHCOMING EVENTS

Tuesday, October 9

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—W. V. Grigson: "The Aboriginal in the Future India".

INSTITUTION OF CHEMICAL ENGINEERS and CHEMICAL ENGINEERING GROUP (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Dr. E. R. A. Merewether: "Industrial Health—Progress, Contrasts and Fallacies".

ILLUMINATING ENGINEERING SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 6 p.m.—H. C. Weston. Presidential Address.

SHEFFIELD METALLURGICAL ASSOCIATION and SHEFFIELD BRANCH OF THE INSTITUTE OF BRITISH FOUNDRYMEN (Sheffield Metallurgical Club, 198 West Street, Sheffield, 1), at 7.0 p.m.—H. O. Howson: "The Formation of Banded Structures in Horizontal Centrifugal Castings".

Wednesday, October 10

ROYAL SOCIETY OF MEDICINE, SECTION OF COMPARATIVE MEDICINE (at 1 Wimpole Street, London, W.1), at 2.15 p.m.—W. A. Pool: "A Plea for the Eradication of Tuberculosis in Cattle in Great Britain" (Presidential Address).

INSTITUTION OF ELECTRICAL ENGINEERS, RADIO SECTION (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. A. H. Mumford: Inaugural Address as Chairman.

SOCIETY OF CHEMICAL INDUSTRY (joint meeting of the NEWCASTLE SECTION with the ROYAL INSTITUTE OF CHEMISTRY) (in the Chemistry Lecture Theatre, Newcastle-upon-Tyne), at 7 p.m.—Dr. H. Baines: "The Choice of Photographic Materials for Scientific Purposes".

INSTITUTE OF WELDING, NORTH LONDON BRANCH (at the South-West Essex Technical College, Walthamstow, London, E.17), at 8 p.m.—"X-Rays and their Use in Weld Testing", Dr. R. J. Barnes: Part 1, "Plant and Equipment", Dr. S. Torrence: Part 2, "Use and Applications".

Thursday, October 11

ROYAL COLLEGE OF SURGEONS (at Lincoln's Inn Fields, London, W.C.2), at 5 p.m.—Sir Howard Florey, F.R.S.: "The Use of Micro-organisms for Therapeutic Purposes" (Lister Memorial Lecture).

INSTITUTION OF ELECTRICAL ENGINEERS, INSTALLATIONS SECTION (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. Forbes Jackson: Inaugural Address as Chairman.

SOCIETY OF CHEMICAL INDUSTRY, ROAD AND BUILDING MATERIALS GROUP and LONDON SECTION (at Gas Industry House, 1 Grosvenor Place, London, S.W.1), at 6 p.m.—Prof. E. K. Rideal, F.R.S.: "Some Physico-chemical Problems in Construction".

ASSOCIATION OF SCIENTIFIC WORKERS, LONDON AREA (in the Caxton Hall, Westminster, London, S.W.1), at 7.0 p.m.—Report on Visit of British Men of Science. Prof. D. M. S. Watson, F.R.S., Dr. W. A. Wooster, and others.

ROYAL INSTITUTE OF CHEMISTRY, LONDON AND SOUTH-EASTERN COUNTIES SECTION (at the Public Library, William Street, Slough), at 7.0 p.m.—Dr. J. M. Walter. "Recent Advances in Plastics".

Friday, October 12

RESEARCH DEFENCE SOCIETY (at Manson House, Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 3.15 p.m.—Sir William Savage: "Public Health and its Debt to Experimental Medical Research" (Stephen Paget Memorial Lecture).

ROYAL ASTRONOMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Prof. Bengt Edlén. "The Origin of the Emission Lines in the Coronal Spectrum" (George Darwin Lecture).

INSTITUTION OF MECHANICAL ENGINEERS (Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—W. G. A. Perring: "The Mechanism of the German Rocket Bomb (V.2)" (Lantern Lecture).

INSTITUTE OF WELDING, BIRMINGHAM BRANCH (at the James Wat Memorial Institute, Great Charles Street, Birmingham), at 6.30 p.m.—Dr. E. G. West: "Developments in the Welding of Aluminium Alloys".

SOCIETY OF CHEMICAL INDUSTRY, SOUTH WALES SECTION (at the Royal Institution, Swansea), at 6.30 p.m.—Mr. F. Gill: "New Physical Methods in Examining Petroleum Products".

BRITISH ASSOCIATION OF CHEMISTS, ST. HELENS SECTION (at the Y.M.C.A. Buildings, St. Helens), at 7.30 p.m.—Mr. H. Pritchard "Chromatography".

Thursday, October 11—Thursday, October 25

ELECTRICAL ASSOCIATION FOR WOMEN Twenty-first Birthda Celebrations, at Dorland Hall, Lower Regent Street, London, S.W.1

October 11, at 11 a.m.—Opening by Duchess of Kent.

October 12, at 2.30 p.m.—Sir Robert Watson-Watt, C.B., F.R.S. "Women and Wireless." Dr. Kathleen Lonsdale, F.R.S.: "A Woman Physicist Looks Back". Sir Harry Railing: "After the Scientist, the Engineer".

October 12 and 13. Annual Conference of the Women's Engineering Society. Miss M. M. Partridge: "The Next Twenty-one Years" (Presidential Address).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on o before the dates mentioned.

SCIENTIFIC OFFICER FOR POTATO INVESTIGATIONS at the Nationa Institute for Agricultural Botany, Huntingdon Road, Cambridge—The Secretary (Oct. 10).

A LECTURER and an ASSISTANT LECTURER IN ZOOLOGY in th University of Birmingham—The Secretary (Oct. 13).

EDUCATIONAL ADMINISTRATIVE OFFICERS (male and female) to dea with universities, adult education, technical colleges, youth activitie and other aspects of the control of German education in the Britis Zone of Occupation—Appointments Department, Ministry of Labou and National Service, Sardinia Street, London, W.C.2, quoting Re No. O.S.1118 (Oct. 15).

TEACHER OF MECHANICAL ENGINEERING SUBJECTS, and a TEACHE OF PHYSICS, at the Acton Technical College, High Street, Acton London, W.3—The Principal (Oct. 15).

LECTURER IN INORGANIC CHEMISTRY in University College, Nottingham—The Registrar (Oct. 20).

LECTURER IN ORGANIC CHEMISTRY at the City of Liverpool Technica College—The Clerk to the Local Education Authority (Oct. 20).

LECTURER IN GENERAL ENGINEERING SUBJECTS, and a LECTURE IN ENGINEERING MATHEMATICS, in the Merchant Venturers' Technic College, Bristol—The Principal (Oct. 20).

CHIEF SUPERINTENDING ENGINEER (Ref. No. C.2840 XA), ASSISTAN CHIEF ENGINEER (Ref. No. C. 2841.XA), MECHANICAL ENGINEER (Ref. No. C.2842.XA), for a paper mill in India—The Ministry o Labour and National Service (Appointments Department), Technic and Scientific Register, Room 670, York House, Kingsway, London W.C.2 (Oct. 22).

LECTURER IN PHILOSOPHY in the University of Birmingham—Th Secretary (Oct. 27).

HARBOUR ENGINEER for harbour construction and maintenanc for the Sudan Railways—The Ministry of Labour and National Servic Appointments Department, Technical and Scientific Register, Roo 670, York House, Kingsway, London, W.C.2, quoting E.1962 (Oct. 31).

DIRECTOR OF THE BRITISH ELECTRICAL AND ALLIED INDUSTRIE RESEARCH ASSOCIATION, 15 Savoy Street, London, W.C.2—The Chairman (Nov. 16).

READER IN PUBLIC HEALTH in the University of London at th London School of Hygiene and Tropical Medicine—The Academ Registrar, University of London, Richmond, Surrey (Jan. 29, 1946)

CHAIR OF NATURAL PHILOSOPHY in the University of Aberdeen—The Secretary (Feb. 15, 1946).

CHAIR OF EXPERIMENTAL PHYSICS AND THEORETICAL MECHANI at Istanbul University—The British Council (Appointments Department), 3 Hanover Street, London, W.1.

CHAIR OF MECHANICAL ENGINEERING, CHAIR OF ENGINEERI TECHNOLOGY, CHAIR OF ELECTRICAL ENGINEERING, CHAIR OF MARI ENGINEERING, CHAIR OF MARINE ELECTRICAL ENGINEERING, and CHAIR OF TELEGRAPHY AND TELEPHONY, in the Technical Unive sity, Istanbul—The British Council (Appointments Department 3 Hanover Street, London, W.1.

CHAIR OF PHYSICS, and CHAIR OF CHEMISTRY, in Ankara Universit—The British Council (Appointments Department), 3 Hanover Stree London, W.1.

LABORATORY STEWARD to take charge of animal house at a canc research laboratory—The Director of Research, Glasgow Royal Canc Hospital, 132 Hill Street, Glasgow, C.3.

LECTURER IN PSYCHOLOGY at the Furzedown Training Colleg Welham Road, London, S.W.17—The Principal.

A LECTURER IN CHEMISTRY, and a LECTURER IN BIOLOGY, at t Polytechnic, Regent Street, London, W.1—The Director of Educ tion.

LECTURER IN SOCIOLOGY at Bishop Otter College, Chichester—T Principal.

TEACHER (man or woman) OF BIOLOGY at the Wolverhampton a Staffordshire Technical College—The Clerk to the Governors, Educ tion Offices, North Street, Wolverhampton.

University College ... PHYSICS DEPT.

DEMOBILIZATION, REHABILITATION AND LAND USE

THE orderly release of men and women from the Armed Forces was rightly given first place in the domestic policy of the Government as outlined in the King's Speech at the opening of Parliament and in the Prime Minister's speech in the debate which followed. Subsequent events such as the sudden termination of Lend-Lease have only further emphasized that demobilization is the first and most urgent domestic issue in Britain.

Speed is indeed the essential factor in the success of any demobilization scheme, and while it can be claimed that the plans set forth in the White Paper last autumn are elastic, administrative action has been slow to give effect to that elasticity in accordance with the new situation. Much has been done, too, to educate public opinion as to the basic requirements in reconstruction plans : that is one outcome of the numerous schemes and plans for the reconstruction of Plymouth, Norwich, Manchester and other cities and towns which have been published during the last year or so. There is general appreciation that Government direction is a first need ; and the scepticism or dissatisfaction with which some pronouncements from the Ministry of Town and Country Planning and also the announcement of a Committee on National Parks have been received, make the more welcome the pledge in the King's Speech to formulate proposals to deal with the key problems of compensation and betterment in relation to town and country planning, as well as to improve the procedure for the acquisition of land for public purposes and to promote the best use of the land in the national interest. Moreover, in the recent War Office indication of its desire, if not intention, to keep its gunnery range at Harlech, we have had another example of the way in which departmentalism may defy the whole purpose of the War Works Commission and jeopardize not only at Harlech but elsewhere amenities, plans for rural improvement, housing, water-supply, road-making and other essential features of a national plan.

The relation of reconstruction plans as a whole to demobilization and the re-allocation of man-power, and the way in which demobilization as determining the available man-power is even more urgent than housing, the restoration of the export trade, or the provision of goods for civilian needs, is well brought out in a broadsheet "Framework of a Four Year Plan" issued by Political and Economic Planning. To what is said there as to the need for a four-year plan embodying a time and progress schedule for economic reconstruction, the main essentials of which are clearly understood by every citizen, the new situation following on the sudden termination of the War with Japan only adds emphasis. The broadsheet assumes that the War in the Far East would end late in 1946, and the priorities with which it is largely concerned and which are of the essence of a four-year plan have now become a matter of great urgency. The grave problems confronting the United Nations Relief and Rehabilitation Administration, the implications of the attempt to rehabilitate Europe or even to relieve distress and prevent famine are scarcely yet understood in Great Britain, and even less in the United States. Until needs are balanced against resources and the maximum national production obtainable with our limited resources estimated, we cannot draw up the man-power budget referred to in the White Paper on Employment Policy, and without which no employment policy can be effective.

It is true that since the *Planning* broadsheet was published the outlook on defence has been radically changed by the advent of the atomic bomb as well as by the collapse of Japan. Decisions on the speed of demobilization, however, do not depend altogether on decisions on the ultimate size of the Armed Forces. Several millions must be demobilized in any event, and we cannot afford the waste of unemployment, whether disguised in uniform or not. Psychological reasons also stress the importance of speed, though here an equal essential is that the Government's policy should be clearly explained to all those whom it affects.

The value of the present broadsheet has not been affected by these fresh considerations, because its presentation of a man-power budget, following on an attempt to measure the total national production and to estimate how it should be divided between consumer goods and services, public and private investment and the other requirements of public authorities, is put forward as an illustration of how the job should be attacked and what is involved in doing it. In particular, the limiting effect which a bold programme of industrial investment must have on the volume of man-power available to meet consumer needs and especially the requirements of distribution and services must be kept in mind. Moreover, the important conclusion that only by some form of control of entry into the distributive trades can enough man-power be made available in the next four years to ensure the re-equipment and modernization of British industry, a rising standard of living, and, with it, an adequate housing programme, is a timely warning.

The estimate of the 'net national production' in this broadsheet is based on the broad assumptions of total industrial employment of levels of 16·1, 16·4, 17·1 and 17·4 millions for 1946, 1947, 1948 and 1949, respectively, as compared with 16·8 millions in mid-1944, and allowing for a net gain of about 1, 2, 3 and 3·5 million men and women released from the Armed Forces and from Civil Defence; an average working week of the same length as in 1938, but increases of 9, 10·5, 12 and 14 per cent, respectively, in the production per man-hour, with the same terms of trade and with net income from foreign investments, at 1938 prices, of £80 million in each year. Assuming further that the Armed Forces will number 4, 3, 2 and 1·5 millions, respectively, in these years at a cost of £720, 540, 360, 270 million at 1938 prices, *Planning* arrives at an estimate of the net national production of £5,450, £5,430, £5,520 and £5,610 million for the four years in question.

This last assumption is clearly the one that will require most readjustment: it will not be easy to satisfy public opinion on the basis of any figures larger than 3, 2 and 1·5 millions in the Armed Forces for the first three years of the period, even if it is necessary to maintain a level of 1·5 millions for a few further years. It should be noted, moreover, that the latter figure is itself approximately double the level at which it has been computed the Armed Forces could be maintained on a voluntary basis with an intake of 300,000 recruits each year on national service for one year, but excluding trained reserves or 'territorials'. More than this is unlikely to secure public support, and it is evident at once that the man-power situation puts severe limits on our defence policy and in itself indicates the necessity for the speediest possible adjustment to a long-term basis if not to the final peace standard when order has been established.

The observations made in the broadsheet on economic demand, which may be said to arise from three sources—consumption, investment and public authorities' demand for goods and services other than investment—and on the priorities to be assigned not only to these needs but also within the categories between production for the home market and production for export, require much less qualification, and lead to the outstanding conclusion that the first post-war years should be years of heavy investment in building and industrial equipment, for this will be the prerequisite of a rise in productive efficiency and in the standard of living. Moreover, if building is to come first so that war-time damage and arrears can be made good as soon as possible, the resources available for the restoration and modernization of industry and of the public utilities will be drastically limited. Priorities will have to be fixed in peace as in war, and certain controls retained to make them effective.

Vital as investment will be, some rise in consumption should also be contemplated, particularly in regard to non-durable goods and the re-stocking of clothes, shoes, furniture, hardware and the like. At the same time, they should be produced in ever larger quantities for export, and this applies no less to investment goods of all kinds. These considerations lead *Planning* to some assumptions about the broad trends of defence, expenditure, consumption, investment and the foreign balance, and to the presentation of a table of national expenditure for the four years in which the net expenditure at 1938 prices increases from £5,450 millions to £5,610 millions, while expenditure on consumer goods and services increases over the period from £3,190 to £3,770 millions, investment expenditure from £160 in 1946 to £800 millions in 1947 and £915 millions in 1949, while public expenditure on other goods and services decreases from £2,300 millions in 1946 to £1,300 millions in 1947 and then to £1,000 millions.

From these general considerations, the broadsheet attempts to draw up a rough man-power budget for the same period, starting from the targets officially indicated for the building and coal-mining industries. For mining, the labour force is put at 830,000 throughut the period ; with 800,000, 950,000, 1,100,000 and ,250,000 in the building industry for the four years, respectively. Allowance is made for contractions in griculture from 1,100,000 to 1,040,000, and in the number of those employed in public service (including Royal Ordnance Factories, etc.) from 1,550,000 to ,450,000 ; while it is assumed that the total labour orce in the transport (and fishing) industries will emain stationary at the present level of 1,250,000, nd that in the public utility services at 200,000. In distribution it is estimated that numbers will increase rom 2,080,000 to 2,300,000, while those engaged in the professions, banking and insurance, domestic and ther services such as entertainment, hotels, restaurants, etc., are put at 1,450,000, increasing progressively o 1,600,000.

With regard to the most effective distribution of he balance of 6,590,000 in 1946, increasing to ,230,000 in 1949, the re-equipment of industry is onsidered the most important task, and since the ulk of this will fall on heavy engineering ; it is considered that, on the whole, no great change is likely n the numbers employed in spite of war-time expansion. The labour force in the munition industries s regarded as likely to fall considerably from its 944 level but to remain above its pre-war size for ome time, and is estimated at 3·9–3·5 millions or the four years, leaving available for the consumer oods industries and "other manufactures", which nclude building materials, 2·7–3·7 millions for the ame period. If building is given first priority, the man-power available for consumer goods production will be strictly limited and will not regain its pre-war evel of 3·8 millions until after 1949.

Commenting finally on this rough man-power basis or a four-year plan, *Planning* emphasizes that man-power is the most valuable of our resources, and we annot afford to squander it either in a plethora of unproductive services or in the pernicious waste of mass unemployment. Provided we take the necessary measures to avoid these dangers ; that we do not starve industry of the man-power and resources needed for its rapid re-equipment ; that we accept he need for a few years 'austerity' compared with pre-war standards ; and that by our skill and initiative we re-establish our position in world trade ; then there is, in the opinion of P.E.P., no unsurmountble economic obstacle to the achievement of an dequate solution of the housing problem and, generlly, of a steadily rising standard of living. To those rovisos there might well be added one to the effect that the priorities must be determined in the right rder, and that the Government, having made its ecisions, should take the necessary steps not merely o implement them but also to see that they are nderstood by the community generally, and that the reasons for any restraint or controls are fully ppreciated and accepted by those whom they ffect.

The importance of these last two points is not easily overstressed. Industrial development, whether n the development areas and trading estates or elsewhere, the housing programme, a national parks policy, and the reconstruction of the war-damaged towns or transport systems, involve control of the use of land, in order that the national resources may be utilized most effectively. It is not merely that sectional and departmental interests, however important, have to be balanced and adjusted with the other national interests the life of which depends on the same natural resource—the land ; but also any reconstruction programme of food, work and homes must be so devised that the use of land will harmonize with all the main interests—the health and welfare of cities, agriculture, industrial development, transport and communications, food policy, forestry development, and national amenities such as national parks and public access to mountain and sea. But while much progress has been made towards the formulation of a national policy, little has yet been done to forge the instruments for giving effect to such a policy, nor have the vital decisions been taken on the main central difficulty—that of compensation and betterment.

Some of the elements in the situation, it is true, have evidently been defined. The Minister of Town and Country Planning has already announced his intention of introducing during the present session a Bill dealing with compensation and betterment, which it may be hoped will clear the ground for the local planning authorities to exercise far-reaching new powers with courage and constructive wisdom in the execution of the numerous plans already formulated. Simultaneously, Mr. Silkin announced that he was appointing a committee with Lord Reith as chairman "to consider the general questions of the establishment, development, organization and administration that will arise in the promotion of new towns in furtherance of a policy of planned decentralization from congested urban areas ; and in accordance therewith to suggest guiding principles on which such towns should be established and developed as self-contained and balanced communities for work and living". This is an important step, and Mr. Silkin could scarcely have made a better choice for the chairmanship of the committee than Lord Reith.

The new committee will have to examine a wide range of problems, especially if "new towns" includes every kind of 'overspill' community which is intended to be more than a mere contiguous dormitory suburb. Meanwhile, Mr. Silkin will himself discuss with local authority organizations the difficult problem of fitting the new urban growth into the existing structure of local government. The committee itself may have to consider the utilization of some type of agency more flexible than a local authority, and subject to more direct social control than private industry, which can harness the efforts of both in promoting the development of communities in which work and homes, economic needs and community life are properly related ; while Mr. Silkin may find it necessary to acquire the power to forbid further industrial development in over-industrialized areas, deleted from the recent Bill, as well as to ensure that no dereliction on the part of local authorities frustrate the best use of land in the national interest.

The steps taken by Mr. Silkin are only a beginning, but they are something to offset the concern aroused by such cases as the Harlech beaches; and it would appear that technical difficulties are not to prevent a high priority being given to the pledge in the King's Speech to deal with the key problem of compensation and betterment. That is an essential step in achieving the programme of reconstruction to which the Coalition Government was no less committed than the present Government. The Prime Minister has shown in his broadcast speeches and in addressing the Trade Union Congress a clear appreciation of the importance of the Government taking the country into its confidence far more than has been possible during the last six years. The *Planning* broadsheet is a valuable aid in that work of educating public opinion; but no educational work, however vital, can be a substitute for appropriate decision at the centre on the crucial issues and the right priorities.

PROBLEMS OF THE MODERN UNIVERSITY

Redbrick and These Vital Days

By Bruce Truscot. Pp. 216. (London: Faber and Faber, Ltd., 1945.) 10*s*. 6*d*. net.

"REDBRICK and These Vital Days" lacks nothing of the charm and vivacity which characterized "Redbrick University". Once again Mr. Truscot moves with the ease of long familiarity and experience among the problems of the modern university, asking searching questions and suggesting persuasive answers, inspired by a vision of the greatness of the university ideal and by much sound common sense. Here, however, his mordant wit is kept in rather firmer check. He replies indeed with spirit to the criticism of some of the strictures in his earlier book; but the present volume has more coherence and plan. There is less straying into side-issues and irrelevancies, and as a result Mr. Truscot presents us with a survey of the university as a part of the educational system as a whole that none should ignore who are concerned that the community should get the fullest value from that great increase in expenditure on the universities to which we are already committed.

A sense of values and a firm insistence on high standards are indeed the dominant notes of this book. It is a plea for quality as against numbers, for the maintenance of the highest tradition of academic freedom, "to know, to utter, to argue freely according to conscience", and for professional conduct and standards worthy of the university autonomy for which he pleads. His severest criticism and firmest warning are ever against conduct or policies unworthy of the highest traditions of the universities of Britain, or which endanger their independent status as national institutions. He urges a levelling up to the best of Britain's university tradition in freedom, resources, standards and spaciousness. His profound respect for the ideals and achievements of 'Oxbridge' are matched by an unmistakable conviction that 'Redbrick' has the capacity to make its own unique but equally worthy contribution to the service of the Britain, and indeed the world, of to-morrow.

The field over which Mr. Truscot ranges is even wider than in "Redbrick University", and on some of the questions his discussion may seem a little perfunctory. Not all his readers will be convinced without further argument as to the adequacy of his prescriptions even when they accept his diagnosis None can mistake, however, Mr. Truscot's determination to put first things first, and where the solutions he suggests are unacceptable, the onus is on those who reject them to provide an alternative which avoids the dangers of which he gives clear warning

Mr. Truscot deals first with the immediate problems of 'Redbrick University', and in his opening chapter he has a trenchant comment on the implications of the wholesale suppression of the arts courses on which we have in the past been wont to rely for the recruitment of several key professions as well as the administrator, whether in the higher ranks o the Civil Service or elsewhere. The fact that the training of those destined for such careers needs to be improved so that they are aware of the significance of scientific achievements and competent to appreciate the bearing of the scientific factors which enter into the problems they are required to handle, or even that it is desirable that those with a scientific training and administrative ability should be encouraged to follow an administrative career, should not lead us to forget that, as Dr. B. Ifor Evans has reminded us, the last thirty years have given a grim warning of the way in which science and technology in the hands of those devoid of a sense of values, which we derive in the main from the study of arts subjects lead to chaos and barbarism. Mr. Truscot pays a deserved tribute to a broadcast of Prof. V. H Galbraith, but the position could not be better put than in Mr. Truscot's own words, and the passage should not be allowed to escape the notice of the Ministers of Education or of Labour. The number of arts students to be released should be governed primarily by the capacity of the universities to complete their training, and that capacity is believed to exceed considerably the 3,000 students whose release has recently been announced.

In the same chapter, Mr. Truscot argues against a policy of large increases in the number or size o the universities of Britain. If more suitable and efficient entrance tests are applied, he questions whether numbers will rise by more than about 10,000 above their pre-war level, and he stoutly challenges the view that there can be at present anything like 60,000 who are kept out of the universities solely because of the cost. Mr. Truscot may tend to underestimate the post-war demand for science graduate if anything comes of the debate on the expansion o scientific and industrial research; though even so part at least of the demand for technologists would be met by the technical colleges and institutes which he would develop. Fundamentally, he is right to insist on the maintenance of standards and that while no one should be debarred by lack of means no one should be entitled to a university education unless he can profit by it. His estimate that if England had sixteen universities averaging 3,000 student each instead of the present eleven and total of 35,00 students all reasonable needs would be met may no be wide of the mark.

The remainder of this chapter deals with topic discussed more fully in his earlier book, such as th sabbatical year and the need for care in making permanent appointments. He suggests that universities should agree generally to make all post-wa appointments temporary except to positions in xistence before the War began, and on the question f salaries he advances reasoned proposals differing onsiderably from those of the Association of Univer-ity Teachers, particularly in his insistence on the lependence of the reputation of our universities on he quality of their professoriate and on the con-equent need to raise such salaries to scales that vill attract and keep men and women of the highest uality. In defence of such standards, Mr. Truscot s uncompromising and ruthless, and when he returns fresh in a later chapter to the case of the idle pro-essor, the 'wigs are already on the green'.

Mr. Truscot sticks to the suggestions already made nd, as in his former volume, his critique of research s shrewd and sound. This chapter, however, should ot be read apart from the rest of the book. The nsistence on the need for reform here is part of the lea that runs through the whole book for high tandards, for the recognition not merely of new eeds and new responsibilities for the nation in the ost-war world, but also of new obligations too for the niversities themselves, chief among which obliga-ions is that of examining any question afresh in the ght of changed conditions—even of principles con-idered as axiomatic and privileges which by long sage had come to be claimed as rights. He claims hat the universities should help to formulate the ew conception of society by their approach to their wn problems, and that the newer universities in articular must trace out their own way, boldly ut surely, with reference to the wants, real or upposed, of emergent society especially in their egion.

Whether he writes of the reform of the curriculum, he distinction between narrowness and specializa-ion, the content of the honours course, academic epresentation, autonomy and the implications of ncreased assumption of financial responsibility by the tate, Mr. Truscot never loses sight of that high leal, and it inspires all his suggestions. If he looks r no greater increase in the numbers of university tudents, he has no hesitancy in insisting on the need r greatly increased endowment. For residential levelopments he suggests that each of the newer niversities will require a non-recurrent grant of bout one million pounds, with a recurrent annual rant of about half a million for open scholarships, esearch and tutorial posts, travel grants and ther facilities, in addition to the immediate increase f the annual grant to all the universities from the resent two millions to ten millions.

No part of the book is more valuable than the oughtful discussion of the implications of a sub-antial increase in the endowment of universities y the State and of the dangers of State control hich follows; and Mr. Truscot champions the eedom of the universities from State control, from ureaucracy, or from party politics, whether that is xpressed as control of the universities themselves a more insidious tyranny over the academic dividual by the university, as stoutly as he does e need for ample financial provision. Mr. Truscot oks ahead himself, and his outspoken book should least stimulate a real attempt to grapple with me problems of academic freedom, university overnment and inter-university co-ordination where ly hard thinking and foresight can avoid serious fficulties or dangers to-morrow.

When Mr. Truscot attacks internal abuses, it is cause of their threat to the real motive power of e universities. Nowhere is this clearer than in his chapter on the university and its region, part of which has already appeared in *The Political Quarterly*. Mr. Truscot repeats his warning that we should regard with suspicion the demand that the university should continually be thinking of 'society', teaching citizenship, stimulating the social consciousness, supplying experts to local industries and the like. This may well provoke a storm of protest; but Mr. Truscot, who sees as clearly as anyone the guiding and steadying influence to the public mind on great issues which a university in a large city may well be, is right. Unless 'Redbrick' preserves its standards of scholarship, safeguards its intellectual autonomy, establishes the right relation between teaching and research, it can never function as the cultural centre of its region in the way he describes in this chapter.

The university, Mr. Truscot suggests, should be a regional power-house, but it must be sure about the nature and source of its power, and avoid diffusing its energy and indeed its life in beneficent but indiscriminate well-doing. A power-house, not a forcing-house; the monastic, not the crusader's tradition—these are the notes on which he passes to discuss as persuasively the implications first of the Norwood, and then of the McNair and of the Fleming Reports. The Norwood Report, for the most part, he welcomes unreservedly, though he points to the danger of allowing the interview, or school testimony, to rank equally with the written examination in the entrance test to the university. He holds, with the Report, that residence at university age is absolutely essential to an all-round education and must become inseparable from university life. He dissents from the report in its classification of the types of freshman, and suggests that five and not three types are to be distinguished, and that some provision should be made for excluding the 'narrow' candidate from academic life unless of exceptional brilliance. Of the allocation of scholarships and of the influence of the universities on the schools, he writes bluntly and at least lays bare the real issues. Whether his argument is acceptable or not, he writes no less appreciatively and trenchantly of the McNair Report, insisting that the fundamental studies and disciplines of all teachers, primary and secondary alike, are, at their apex, the concern of the universities, and he warmly welcomes the creation of the Foundation for Educational Research.

Finally, in the two chapters in which he discusses the public school problem and the Fleming Report, Mr. Truscot suggests as his own solution of this problem that we should concentrate on the task of raising the standards of day secondary schools to the level of the best public schools: to provide a brilliant or an industrious boy with the best of conditions for his work, tuition by highly qualified and technically skilled masters, contact with minds which will stimulate and enlighten his own, hygienic conditions in which to work, a well-stocked library, playing-fields for recreation, and the education which team games can give. Once again, Mr. Truscot gets down to the essentials, and though these concluding chapters are written from the point of view of the university itself, and the ways and means of ensuring that our universities neither miss any appreciable fraction of those who could profit by a university education nor be cluttered by those who are unable to do so, they will be read with interest and profit by many parents or teachers whether the boys and girls with whom they are concerned are proceeding to a university or not.

R. BRIGHTMAN.

COLOUR FOR ANALYSTS

Colorimetric Analysis

By Noel L. Allport. Pp. xii+452. (London: Chapman and Hall, Ltd., 1945.) 32*s.* net.

ALTHOUGH the author of this book is described—and presumably describes himself—as a "pharmaceutical research chemist", it is clear that only an analytical chemist, in the severest sense of that term, could have produced it. Mr. Allport is, of course, an active analyst and his work is well known and highly appreciated among those who practise analytical chemistry. He has, in fact, produced precisely the kind of book that they would have expected of him—practical, helpful, critical, judicious.

Mr. Allport is obviously not to be reckoned among the old-fashioned chemists who have an acute feeling of misery—and even indeed a marked conviction of sin—if they finish an analytical procedure with anything but a burette or a balance reading. On the other hand, he would certainly have little mercy on the 'colorimetric' enthusiasts who chose to make measurements of colour absorption the end of every analytical procedure, even when methods of greater accuracy or greater ease (or both) are available. But he has selected, under five major headings—metals; acid radicals; substances of clinical and biochemical significance; alkaloids, hormones and vitamins; and miscellaneous substances—a series of colour reactions, all found by himself or known by him to be suitable for application to quantitative purposes with the degree of accuracy required. He warns the user in his general introduction both of the relatively low precision of colorimetric analytical methods, using 'precision' presumably in the American Chemical Society's defined sense of reproducibility, and of their liability to interference "by extraneous substances", which must affect the specificity and therefore the accuracy of the method, using 'accuracy' again in the sense of nearness to correct value.

There are, naturally enough, many well-known methods omitted, but no doubt always for a very good reason. Thus, it is obvious that a method for cholesteryl esters, as distinct from cholesterol itself, is absent because Mr. Allport does not think that there is one good enough to put forward. On the other hand, he has not hesitated to give a colorimetric method for sulphates in blood, where the micro scale of operations makes the classical methods, still to be preferred for most purposes, inferior to the colorimetric, if indeed available at all.

The book gives precise practical details for preparing solutions of which the colour intensity is to be compared with that of a standard, but very wisely confines itself to the description of the chemical analytical procedures involved, and omits the description and advocacy of particular kinds of apparatus, 'colorimeter', absorptiometer, spectroscope, on the correct assumption that they would be out of place in a book of this scope. Indeed, there would be no room to include such matter without making the book unwieldy. It is surely sufficient that Mr. Allport has covered a range of analytical methods for materials ranging from aluminium to vitamin A, from barbiturates to benzoyl peroxide, from vanadium to pilocarpine, from nitrates to saccharin.

The book is admirably produced and written in simple but unambiguous English. One may perhaps doubt whether Mr. Allport, or anyone else, ought to write "much data", but I have not noticed any other hint of solecism. It is, however, worth noting that Mr. Allport, severely practical as always, has take up a position that, if not exactly a Promethean-lik defiance of Zeus's thunderbolts, does at least sugge the cocking of a snook at the Publications Committe of the Society of Public Analysts and Other Analytic Chemists, of which important body he is himself member! For he uses throughout his book the ter *colorimetric* to refer not to "measuring the colour light . . . under certain conditions", stated by th Committee to be the legitimate use, but to processe that are really those of colour comparison or absor tiometry. As Mr. Allport doubtless shares the Con mittee's views that it would be nice to give up th misuse of the term colorimetry, but that it is n possible to do so now, might he not include th scientific definitions of the relevant terms, and th reasons for or against using them, in subseque editions of his book? Whether he does so or no however, those editions will be deserved and welcom

A. L. BACHARACH.

SCIENCE AND PIG-KEEPING

Pigs

Their Breeding, Feeding and Management. By V. Fishwick. Revised edition. Pp. 222+20 plate (London: Crosby Lockwood and Son, Ltd., 1945 12*s.* 6*d.* net.

PIGS in Great Britain are at the moment under cloud owing to their being in competition wit man for cereal foods, their present numbers bein only about 36 per cent the pre-war population. Sin world production and transport of cereals, howeve is likely to increase again before the increased supp of meat from other animals meets the world deficienc in this product, and since pigs breed and matu rapidly, the pig should soon come back into its ow again. The appearance of this book by V. C. Fishwi on the breeding, feeding and management of pigs shoul therefore be particularly opportune; moreover, it is most suitable book for those people back from the Forc who wish to take up pig-keeping on modern lines.

Although based on scientific research and exper ment, the treatment is essentially practical, for th author is himself in charge of an experimental p station and has had to incorporate results of mode scientific research into practical pig husbandry.

There is much also in the book to interest th student of biology; for example, the factors whi influence the growth of suckling pigs are describe how the pigs in a small litter usually take the forwa teats and grow better than those which have t hinder ones in a large litter. The factors which affe anæmia are also dealt with in detail, since this troub is of common occurrence in young pigs. The deta of the qualities required in a high-grade bacon p are described; and results of feeding experimen are given, including rations and systems of feedi adopted during the War with the object of reduci to a minimum the cereals used. Experiments on t effect of feeding on the quality and melting poi of the fat are also referred to, and there is a chapt on the principles of feeding as applied to the pi A chapter on "Policy" includes such topics as indo and outdoor methods of keeping, and division production between the pork and bacon marke Methods of housing and costs are also dealt with.

The book gives a simple account of the ways which science can be applied in pig-keeping.

JOHN HAMMOND.

THE CORROSION OF METALS

THE summer meeting of the London and Home Counties' Branch of the Institute of Physics was held on July 7, in the Physics Department of the Imperial College of Science and Technology, and took the form of a discussion on "The Corrosion of Metals".

In a brief opening address, the chairman, Dr. S. Whitehead (acting-director of the British Electrical and Allied Industries Research Association), gave a broad survey of some of the main aspects of corrosion which, he said, may be regarded as the main disadvantage from which metals suffer when in competition with non-metals for industrial use. Many cases of corrosion of practical importance in industry are electrochemical in character; this type of corrosion can arise as a result not only of contact potential differences between different metals, but also of local variations in ionic concentration where an electrolyte is in contact with a single metal. The long-line corrosion effects observed in buried cables and water-mains are due to short-circuited concentration cells of this type. Electrolytic corrosion may also occur as a result of leakage currents from electrical installations. As a rule, the corrosive effects of A.C. leakage currents are many times less than those of an equivalent D.C. current; but there is some danger that an A.C. current may be partially rectified at joints in the pipe or cable. The practice of electrically bonding adjacent pipes and cables buried in the soil can be beneficial but may be the reverse; in some cases the balance of potential may thereby be so upset as to produce harmful corrosive conditions.

Dr. W. H. J. Vernon (head of Corrosion Section, Chemical Research Laboratory, D.S.I.R.), who discussed controlling factors in atmospheric and immersed corrosion, said that it should be recognized that most common metals are in a metastable condition and that corrosion is merely the transition back to the stable state. In order to prevent and counteract corrosion, it is essential to appreciate the factors governing the reaction. A broad distinction can be made between 'promoting factors' that initiate corrosion and 'controlling factors' that determine its velocity when once begun. In most cases the key to adequate preventive action is to be found in knowledge of the major controlling factor.

Dr. Vernon amplified his remarks with reference to the two main types of corrosive attack by electrolytes, namely, (1) the hydrogen-evolution type, and (2) the oxygen-absorption type. The former occurs in the case of the more electronegative metals when immersed in acid solutions, the cathodic reaction being:

$$2H^+ + 2e \rightarrow 2H \rightarrow H_2.$$

Here, providing there is no falling off in the rate of supply of acid to the metal, the controlling factor is the formation of obstructive films at either electrode. This rarely occurs at the anode; but obstruction to the cathodic reaction often arises as a result of the hydrogen overpotential. As a result, corrosion of this type may be reduced by the avoidance of impurities of low hydrogen overpotential in the metal itself.

Corrosion of the oxygen-absorption type is usually associated with the less electronegative metals and neutral electrolytes, the cathodic reaction being

$$2H^+ + 2e + O \rightarrow H_2O \text{ or, } 2e + O + H_2O \rightarrow 2(OH)^-.$$

In this case there is a much greater chance of the formation of an obstructive film at the anode, that is, of anodic polarization. Very commonly, however, the controlling factor is provided by the rate of access of oxygen to the cathodic parts of the system. Accordingly, corrosion of this type can often be controlled by preventing oxygen access, either by de-aeration or by the use of closed systems of water circulation. Incidentally, as an interesting scientific development, it has been found possible to devise an accelerated method of testing, in which the rate of corrosion is markedly increased by the use of oxygen under pressure.

Turning to atmospheric corrosion, Dr. Vernon pointed out that there are two main types of reaction: (1) metal-liquid reactions, and (2) metal-gas reactions. It is a common error to assume that reactions of the former type are analogous to those pertaining to conditions of complete immersion. This is not so because, although the promoting factors may be the same in both cases, the controlling factors are different. The rate of supply of oxygen, usually the controlling factor for corrosion of the oxygen-absorption type under conditions of complete immersion, no longer controls the metal-liquid reaction in atmospheric corrosion, because in the latter the thin films of moisture in contact with the metal are saturated with oxygen. Consequently, the physical and chemical properties of the corrosion products are generally the controlling factor; in some cases, the rate of supply of water to the surface is decisive.

As an example of metal/gas reactions, Dr. Vernon cited the corrosion of nickel by a dry atmosphere containing sulphur dioxide. In this case the initial reaction is an adsorption of sulphur dioxide at the surface, leading to the formation of sulphuric acid according to the equation:

$$2SO_2 + O_2 + 2H_2O \rightarrow 2H_2SO_4.$$

Whether a metal-liquid reaction or a metal-gas reaction will occur is mainly determined by the humidity of the atmosphere. Probably, for each metal there is a critical humidity, below which corrosion is of the metal-gas type and above which corrosion is of the metal-liquid type. Dr. Vernon illustrated the distinction, and also the effect of suspended solid particles, which is a peculiar feature of the atmospheric corrosion of iron or steel, by means of a series of experimental curves for the corrosion of iron in atmospheres of increasing humidities and of differing degrees of pollution. He concluded with a few remarks on the metal-gas reactions controlling the formation of the primary oxidation films below the critical humidity; the four types of oxidation/time curves so far observed—rectilinear, parabolic, logarithmic and asymptotic—are all amenable to mathematical analysis and can be interpreted in terms of the physical properties of the respective oxide films.

Dr. D. H. Bangham (British Coal Utilisation Research Association) contributed a note on the reaction between copper and oxygen, based on experiments carried out by Bloomer and himself many years ago. This has been concerned with the mechanism of the initial formation of the cuprous oxide film in the oxidation of copper and involved a series of determinations of the rate of oxygen absorption at progressively decreasing temperatures and pressures. At sufficiently high temperatures the oxidation process was found to follow the normal parabolic law, but, as the pressure and temperatures are reduced in successive experiments, the character of the oxidation/time curve changes and a marked induction period is observed. The most interesting fact, however, is that in the case of tests at the lowest temperatures and pressures on cold-worked copper strip, as distinct from the usual specimens, which are annealed, a distinct periodicity in the oxygen absorption has been observed, the pressure within the apparatus oscillating between maximum and minimum values for prolonged periods. To explain the phenomenon it appears necessary to suppose the formation of an unstable mobile copper-oxygen adsorption complex:

$$\text{Cu (strained)} + O_2 \rightarrow [\text{Cu}, O_2] \text{ (mobile)} \rightarrow \text{Cu (unstrained)} + O_2.$$

In these experiments the pressure oscillations did not greatly exceed the reading error of the McLeod gauge; but other cases have more recently come to light where the same basic assumptions are necessary in order to explain first-order effects. Thus Frl. Leipus found that silver mirrors deposited chemically on glass become particulate at relatively low temperatures (implying migration of silver atoms) in the presence of oxygen but not in its absence.

Dr. J. C. Hudson (official investigator to the Corrosion Committee of the Iron and Steel Institute) presented a short paper on the corrosion of iron and steel, with particular reference to the work of the Corrosion Committee. The Corrosion Committee, which was founded in 1928 as a joint research committee of the Iron and Steel Institute and the British Iron and Steel Federation, under the chairmanship of the late Dr. W. H. Hatfield, now includes, in addition to the main committee (chairman, Mr. W. J. Dawson), five sub-committees, dealing with specific aspects of the corrosion problem, as affecting iron and steel. Of these, four, the Atmospheric Corrosion Sub-Committee (chairman, Mr. T. Henry Turner), the Marine Corrosion Sub-Committee (chairman, Prof. J. E. Harris), the Industrial Waters Corrosion Sub-Committee (chairman, Dr. J. W. Jenkin) and the Sub-Committee on the Corrosion of Buried Metals, are concerned with corrosion in the media respectively denoted by their titles. The fifth sub-committee, the Protective Coatings Sub-Committee (chairman, Mr. T. M. Herbert), is engaged on the important task of studying protective coatings and processes for iron and steel exposed to all media alike. In addition, the Committee has conducted considerable fundamental and laboratory research on corrosion, in which respect it enjoys the advantages of close liaison with the important corrosion-research schools at Cambridge and at the Chemical Research Laboratory, with which Dr. U. R. Evans on one hand and Dr. W. H. J. Vernon on the other, are closely associated; reference should also be made to the work of the late Dr. G. D. Bengough in this field.

After a brief description of the experimental procedure adopted in the Committee's researches, in which a special feature is the conduct of tests under actual service conditions wherever possible, Dr. Hudson proceeded to state a few of the main conclusions drawn from the results.

The rate of general corrosion of ordinary mild steel in the open air varies according to the atmospheric pollution and humidity, in conformity with the principles already enunciated by Dr. Vernon in his paper. Where both factors are low, the corrosion-rate is almost negligible; for example, at Khartoum, the rate is about 0·02 mil (thousandths of an inch) per year. Under conditions of high humidity in the tropics, the rate remains slight in the absence of marked industrial pollution, figures of about 0·5 mil/year being observed. In British climates, where the atmospheric humidity and rainfall are conducive to corrosion, the rate of attack is largely conditioned by the atmospheric pollution, with the result that it varies from about 1 mil per year in rural and marine atmospheres to about 4 mils per year in a highly polluted industrial one. These rates of corrosion in the open atmosphere show a tendency to decrease with time; as a rule, no appreciable pitting is observed under normal conditions of outdoor exposure.

When completely immersed in sea-water, mild steel has been found to corrode at rates of 4–5 mils/year, while 1·5 mils/year is a representative figure for the rate of general corrosion of mild steel by clay soils. In these media, however, pitting is an important factor, and the rate of maximum penetration may exceed these figures considerably.

The influence of composition on the corrosion-rate of the ordinary irons and steels produced in large tonnages for structural purposes, as distinct from the highly alloyed rust-resisting steels proper, is most marked in the case of complete exposure in the open air. Under such conditions, ordinary British wrought irons are some 20 per cent less corrodible than ordinary mild steel; they appear to owe this superiority largely to their high slag content, because Swedish wrought iron, which is prepared from high-grade ores smelted with charcoal and is of high purity, is up to 50 per cent more corrodible than mild steel under the same conditions. Moreover, ingot iron, a dead mild steel with the lowest practicable carbon content, shows no superiority to ordinary mild steel under these conditions.

The addition of small percentages of alloying elements to mild steel or wrought iron produces an appreciable improvement in corrosion resistance. In the open atmosphere, a steel containing 0·2–0·5 per cent copper loses approximately 20 per cent less weight than one containing no copper. The joint addition of 0·5 per cent copper and 1·0 per cent chromium produces a greater improvement, and doubles or trebles the corrosion resistance of the steel.

Dr. Hudson then gave a short account of the work of the Protective Coatings Sub-Committee. The most important protective coatings for iron and steel fall into two main groups: (1) paints, (2) metallic coatings. The earlier work of this Sub-Committee was devoted to a study of protection by means of paints, with special reference to the effect of the surface preparation of the iron or steel prior to painting. The results were summarized in a brochure entitled "The Protective Painting of Structural Steel" published by the Iron and Steel Institute. The main conclusions to be drawn from this work are that (1) the best results can only be obtained when paint is applied over properly prepared surfaces from which all rust and mill-scale have been removed; this is best accomplished by pickling or shotblasting; and (2) in many circumstances, particularly where paint is applied to a weathered and wire-brushed surface, it is important to use an inhibitive primer, such as one containing red lead.

The Protective Coatings Sub-Committee is now extending its studies of protective painting to include the formulation of the paints themselves. This work is being conducted in collaboration with the National Federation of Associated Paint, Colour and Varnish Manufacturers of the United Kingdom; technical details of the programme are in the hands of a joint technical panel under the chairmanship of Mr. F. Fancutt, consisting of three representatives of the Sub-Committee and three representatives of the Federation. The first series of tests arranged by this Panel will be concerned with priming paints for heavy structural steelwork, and is about to commence.

The use of metallic coatings for the protection of iron and steel against corrosion has increased considerably in recent years, because a larger number of metals and alloys has become available for the purpose, owing to developments in the means by which it is possible to apply them; for example, zinc can now be applied by cementation (a diffusion process in the hot state), electrodeposition, hot-dipping, or spraying. Accordingly, the Protective Coatings Sub-Committee decided in 1940 to undertake a systematic investigation of the behaviour of protective metallic coatings as applied to mild steel when exposed both to atmospheric and to marine conditions. Coatings of five metals, aluminium, cadmium, zinc, lead and tin and of two alloys, 82/18 cadmium-zinc and 88/12 lead-tin ('terne'), are included in the tests, and a report on the results of observations during the first four years exposure will be published shortly.

The work of the Marine Corrosion Sub-Committee has included an investigation of formulated anti-corrosive paints for the protection of iron and steel under conditions of complete immersion in sea-water; paints in a modified phenolformaldehyde/stand oil medium, pigmented with basic lead sulphate, in admixture with white lead, aluminium and other pigments, have been found particularly suitable for this purpose. The study of marine corrosion is indissolubly connected with that of fouling, and the Sub-Committee has a team of investigators working in this field also, at first under Dr. (now Prof.) J. E. Harris and at present under Mr. K. A. Pyefinch, in the laboratories of the Scottish Marine Biological Association, Millport.

Mr. P. T. Gilbert (British Non-Ferrous Metals Research Association) discussed various aspects of electrochemical measurements in corrosion studies and described in detail a multiple-recording apparatus which he has devised in collaboration with Mr. A. B. Winterbottom to record the variation with time of the electrode potential of corroding metal couples. This apparatus can be used for simultaneous tests on four complete couples and takes twenty-one individual records per cycle, including the potential differences between each member of each couple and a reference electrode, the corrosion current in each cell, together with various necessary subsidiary measurements of temperature, etc. The recording apparatus is a Cambridge thread recorder, dotting every ½ min., so that each individual reading is repeated at intervals of 10½ min.; the selection and sequence of the readings is controlled by a Post Office selector switch.

Mr. Gilbert discussed a number of general points relating to the design of apparatus of this type. The choice of reference electrode is important; the conditions of use in this case are rather severe for the usual types of reference electrode, and in addition it is desirable to avoid any possible contamination of the corrosive solution. The silver/silver chloride electrode fulfils these conditions most satisfactorily; it retains a constant potential provided that the chloride ion concentration in the solution does not vary. The choice of apparatus for the actual potential measurements is governed by the desirability that it should involve tapping the minimum current possible from the cell so as to avoid interference with the course of corrosion. This has been accomplished by using an electrometer valve circuit, which takes a negligible current of the order of 10^{-15} amp.

The supply of a stable voltage to the valve potentiometer over the fairly long periods covered by the experiments caused trouble at first, when the investigators relied on a 10-volt battery, so they constructed a circuit for ensuring a relatively constant voltage from a mains supply. Accurate measurement of the corrosion current may also present difficulties, owing to the complication introduced by the resistance of the ammeter needed to measure it; Mr. Gilbert described two methods of eliminating this factor.

The apparatus has been applied to a study of the variation in the electrode potentials of zinc and iron, when immersed in tap-water in increasing temperatures up to 85° C., the atmosphere over the solution being varied so as to include various mixtures of oxygen, nitrogen and carbon dioxide. The results have not yet been published, but information of the greatest interest has been obtained on the conditions under which in hot water, zinc becomes more noble as the temperature of the water rises and iron less so, with the result that the potential difference between these two metals becomes reversed. Obviously, this has an important practical bearing on the use of zinc coatings for the protection of steel parts used in hot-water systems, as it represents a complete reversal of the normal state of affairs in which galvanized coatings protect the iron or steel to which they are applied by sacrificial electrolytic action. In view of its importance, the matter is being investigated further.

In the last paper, Dr. W. G. Radley (controller of research, Post Office Engineering Department) described some practical instances of corrosion in telecommunication plant. The prevention of corrosion is an important problem to the Post Office, two typical sources of trouble being (1) the corrosion of the lead sheathing of buried cables, and (2) the corrosion of wires in telephone exchanges.

Dr. Radley said that, although all underground cables are laid in conduits, this does not eliminate corrosion, because no conduit is water-tight and the ground-water percolates in. Corrosion of the lead sheathing is of two main types, stray-current electrolysis and direct attack by ground-water. The solution of problems of stray-current electrolysis depends on tracing the leakage currents responsible for it to their source. Methods of determining stray currents by means of earth electrodes, such as that of Schlumberger, are not readily applicable to cables enclosed in a conduit, and the Post Office relies on simultaneous measurement of the current in the sheath at two points a short distance apart. For this purpose a highly sensitive but robust galvanometer is used, by means of which continuous readings of the stray currents can be recorded photographically. More recently, the possibility has been explored of making direct measurements of potential differences along the sheath by means of non-polarizable electrodes.

Chemical analysis and microscopic inspection of the corroded sheaths often give a clue to the nature of the corrosion; for example, in the absence of any abnormal concentration of chlorine ions in the soil water itself, it can generally be concluded that the presence of 5 per cent or more chlorine in the corrosion product is an indication of corrosion of the stray current type.

Attempts to reduce the attack by the substitution of certain lead alloys for pure lead have not so far resulted in any decisive improvement and, although the use of other materials such as thermoplastic synthetic resins has been suggested, no satisfactory substitute for lead sheathing has been found. Laboratory tests show that the addition of silicates, phosphates, chromates, tungstates and molybdates reduce the plumbo-solvency of ground-waters, and since 1931, attempts have been made to make practical use of this fact by the incorporation of sodium silicate in the petroleum jelly used as a lubricant on cables. As a result, in localities where corrosion is mainly chemical, there has been a considerable increase in cable life.

As regards the corrosion of wires in telephone exchanges, Dr. Radley mentioned instances in which extensive failure occurred in unattended rural exchanges within a period of ten years. It is difficult to propound a theory accounting adequately for this corrosion, but humidity, the presence of electrolytes in the insulating wrappings, and potential differences between wires that are touching are contributory factors. Variations of atmospheric humidity are inevitable in exchanges of this type despite air conditioning, and under certain conditions condensation of moisture may occur on parts of the apparatus. Electrolytes are present in all cotton wrappings, but it has been found that they can be eliminated to some extent by washing the wrappings. The practical value of this process is under investigation. Cellulose acetate and acetylated cotton have a lower ash content than cotton and are used as the inner wrappings in place of natural silk.

In the course of the ensuing discussion Mr. J. S. Forrest gave some examples of corrosion of overhead power lines, Mr. Clarke discussed the effect of oxygen in solution on the rate of corrosion, and Mr. A. B. Winterbottom made a mainly mathematical contribution on the use of an optical method for the study of film formation.

SEX EDUCATION: AIMS, POSSIBILITIES AND PLANS*

By CYRIL BIBBY

We come now to what many people will regard as the crux of the matter—when the appropriate facts have been encouraged, what may we expect to be the outcome in terms of sexual behaviour? What, indeed, do we *wish* to be the outcome?

We have to recognize that in Great Britain to-day there is a wide divergence of opinion on questions of sex morality, and in particular, on the question of pre-marital intercourse. For those of our fellows who accept the Church's teaching in its entirety, no queries will arise about the validity of the marriage institution. But increasingly young people are demanding some other justification for it, and those concerned with sex education must either find the justification or honestly admit that they know of none. I believe, however, that the search is not a very difficult one.

Those who see no intrinsic evil in sex may well feel that in a new Utopia the institution of marriage would have no place, that sex relations would be so governed by universal harmony that any contractual basis for living together would be quite unnecessary. But we are not living in a Utopia of perfect beings, and most of us, I imagine, feel that in our present society the married state has a good deal to be said for it.

I believe, however, that a disservice is done to the cause of sexual morality by those who fail to recognize any gradation in standards of behaviour, and lump together all types of pre-marital intercourse under the omnibus title of 'fornication'. I feel some impatience, moreover, with those who seek by their statements to convey the impression that young people to-day, in contrast with the virtuous youth of their own generation, are sunk in sexual vice. It might restore them to a sense of perspective were they to read the words of Alcuin of York, written before ever William of Normandy set foot on these shores. "Since the time of King Aelfwold . . ." he wrote, "the land has been absolutely submerged under a flood of fornication, adultery and incest, so that the very semblance of modesty is entirely absent." Substitute the name of any recent monarch, and there is the gist of many a modern lamentation.

Fulmination, I feel, is a good deal less effective with young people than reasoned argument. It is my experience that the much maligned youth of to-day *will* pay some attention to the views of a sympathetic adult who seeks to persuade them that not all conventions of sex behaviour are hypocritical and not all restraints puritanical. Let us not delude ourselves, however, that even with the most reasoned arguments in the world, all pre-marital sex relations would disappear. No amount of mere talk will of itself dam up the sexual urge of lusty youth. Far-reaching social changes are needed too, and among them is the removal of the all-too-many barriers to early marriage. Equally important is the need to give young people the feeling that they have some future and that there is something for which it is worth while to postpone their sexual satisfaction; to assure them that there is something that they can give to society and which will give them an honoured place in it, to inspire in them some burning sense of constructive social purpose.

One last word about my suggested definition of aims. I stated that sex behaviour should be according to a rationally determined code, but I do not prophesy what that code will be. It would be possible for us so to condition each new generation that it almost automatically thought and felt as its rulers desired: experiment along these lines achieved some considerable degree of success during the last twelve years in Nazi Germany. But, for me at any rate, no such reflex subservience to an authoritarian moral code is included in the aims of sex education. I am content to teach the facts as well as may be, to encourage an open and healthy attitude to sex, to insist on the need for determining conduct rationally —and to have faith that a generation so educated will be at least capable of taking correct moral decisions and making correct moral judgments.

When we leave the definition of aims and begin to draw up definite plans for action, there are, it seems to me, several dangers that must be avoided.

The first is that of Utopianism. There is a great temptation in sex education, as indeed in education generally, to draw up magnificent schemes that are totally irrelevant to the particular social setting within which they are to be put into practice. Let our plans, therefore, be impregnated through and through by an appreciation of what is possible and desirable here and now, not what might be in a brave new world.

---

* Continued from page 414.

The second danger is that of wasting energy on barren argument about whose job sex education is. For too long parents and teachers and medical practitioners have been, to use an Americanism, 'passing the buck' to each other. Sterile disputation about the precise allocation of degrees of responsibility must give way to serious preparation for getting on with the job in hand and to close collaboration between all who have any part to play.

Another danger is that of over-emphasizing sex and isolating it from the rest of life. To this danger some of the early pioneers fell prey. The perhaps inevitable result of their determination to bring sex into its place in the educational picture was that they painted a canvas on which it loomed over-large. In their rightful insistence that children should not remain in ignorance, they tended sometimes to overload them with information beyond the bounds of their curiosity, intellectual ability or emotional understanding. This tendency must be avoided. Sex education, like health education and character training generally, should permeate the whole of life. The better it is, the less obvious it will be. It will just fit in naturally and inconspicuously into the ordinary life of home, school and community, and will be noticeable only to the degree to which it is imperfect.

Never has the mental atmosphere of the country been so favourable to sex education as now, and now is the time to crystallize support. Talks to public meetings, men's and women's guilds, educational and other discussion groups, and so on, should be arranged in each area. Radio talks, film shorts, posters, newspaper advertisements, etc., can be used to a similar end on a national scale. If this were done with energy and determination, I believe that all opposition to sex education, except that of the confirmed obscurantists, could be overcome within a very short period.

There is another immediate problem that needs mentioning. While we are perfecting our long-term plans and awaiting their fruition, our schools send out into the world each year vast numbers of children who have had no sort of reliable sex education. We cannot afford to be perfectionists and do nothing because we cannot do the best. As a temporary measure, therefore, talks on sex should be arranged in youth clubs and the like, and specially devised lessons given in the schools. But the sooner we get rid of this patchwork procedure, the better.

We must concentrate a good deal of attention on the education of the educators, so that a continuous scheme of sex education may be put into practice at the earliest possible moment. Long-term plans must nclude drastic alteration in school, university and raining college curricula—but we cannot wait for hat. Side by side with these changes must go the rganization of immediate help to present parents, eachers, youth leaders, medical men, nurses and eligious and social workers. What can be done to give such help?

I would agree with Charles Dickens when he wrote: 'We thought that, perhaps, it is right to begin with he obligations of home, sir; and that, perhaps, while hose are overlooked and neglected, no other duties an possibly be substituted for them", and shall herefore consider parents first. Rosy optimism is worse than useless, and it must be recognized that many present parents are too ignorant to explain the acts of sex to their children, too indolent to remedy heir ignorance, and too tangled in their emotional attitudes to be able to do much were they very encyclopædias of sexual knowledge. But not all present parents. Many are well informed and many others anxious to inform themselves. Many have a thoroughly healthy attitude to sex and many others are eager to attain it. With such there are great possibilities. Courses could be arranged for the parents of new entrants to the nursery or infant school, and perhaps again when their children pass on to the secondary stage. More systematic help and guidance could be given to expectant and nursing mothers at the clinics and welfare centres. The matter could be dealt with at village institutes, community centres, co-operative guilds and the like.

So far as teachers are concerned, it is reasonable to expect a much more thorough preparation. Most of what is needed to provide the necessary background to sex education should indeed be part of the normal professional training course. All teachers need an understanding of the child's bodily, intellectual and emotional development, and this can only be based on a knowledge of fundamental physiological and psychological principles. It would also be very valuable for teachers to have an understanding of the sexual behaviour and problems characteristic of children of various ages, and to study in more detail those of the age-range which they are specially preparing to teach. Moreover, since sex education in the school will be effective in proportion as sex education in the home is not neglected, teachers need also to understand something of the problems of home life and infant training. All teachers need also to be equipped with certain fundamental data which will enable them to answer adequately questions which happen to arise in their school lessons. This implies that all teachers in training—whether they are going to teach the functioning of living things or the structure of dead languages—should take a course in human and social biology. Some training is needed also in the technique of sex education. The ways in which the various subjects of the school curriculum may be utilized as media of sex instruction, the value of various extra-curricular activities in the development of character, the effect of the general school routine and tone upon the fixing of sex habits and attitudes—all these should be studied. Specialist teachers, such as biologists, will naturally need a still fuller preparation.

If it be objected that there is no time to study all this, so much the worse for the very inadequate period of training which is still considered sufficient for teachers.

In the future we may have such teachers, but there are few to-day. In the meantime, then, what can be done? Most present teachers of biology have the background which will enable them to pick up the necessary extra factual knowledge quite quickly, and many of them have the requisite personality. What is most needed in such cases is courses of instruction by specialists, dealing in part with those physiological and psychological aspects of sex which are not normally covered in university and training college syllabuses, and in part with the technique of sex instruction in the school. Such courses will not make first-rate sex educationists of all who attend them, but at any rate some of the teachers will then be competent to deal with the subject with their pupils, and the others will at least have some understanding of what is aimed at.

Now what of youth leaders? It is encouraging to note that the 1944 McNair Report comments that:

"There are three matters which are of great significance for young people—religion, politics and sex. They are certain to arise, sooner or later, in any discussions with boys and girls on social conditions or their own physical, mental or spiritual problems. Leaders must therefore be prepared to face them." When the county colleges envisaged in the new Education Act become a reality, they will presumably provide a useful channel for guidance in these matters. In the immediate future, we shall have to do the best we can under the present very difficult conditions of inadequately trained youth leaders, poor club accommodation and so on. The difficulty is, moreover, accentuated by the fact that most of the club members will have received little or no sex education in earlier years. Apart, therefore, from definite lectures to the young people themselves, such as were suggested earlier, the main advance must be that of giving a general background of knowledge to youth leaders, which will help them to deal more effectively with the problems of behaviour which always arise in youth work and to give helpful personal guidance to their club members.

We must recognize, however, that most young people spend only a few hours each week in their youth organization and the major part of their day-time at work. Parallel with what is done in the club, therefore, it seems essential to tackle also the environment in factory, shop and office. The co-operation of industrial welfare workers and of shop stewards and trade union officials should, therefore, be enlisted in any balanced programme of sex education work.

Now let us consider the medical profession. What part has it to play in sex education? The quite common opinion that medical men are peculiarly qualified to give sex instruction is, I suspect, an aftermath of the feeling that sex is in some way abnormal, and therefore to be handled only by medically qualified persons. This idea, I hope, is dying out rapidly and the role of the medical practitioner should be estimated without prejudice.

Any other than elementary instruction on the venereal diseases is clearly the medical man's province, as are other problems of sexual pathology; while a great deal of work in preparation for marriage, concerning the technique of intercourse, the practice of contraception and so on, is largely medical in nature. Medical practitioners also, particularly those specially concerned with the young child, should be able to give much helpful advice to parents.

But those medical practitioners who aspire to be sex educators will need to give careful study to the psychological aspects of sex as well as to its physiology; and they will need sociological insight too. Sex relations and marriage are not purely medical problems. Equally they are problems of politics and economics, of passion and of friendship, of intellectual companionship and mutual respect. Is it too much to hope that medical training might in the future pay more attention to these and other related matters? No doubt, as in the training of teachers, there is the difficulty of already overcrowded syllabuses. But would not some little study along these lines be of more value to the general practitioner and his patients than a painfully acquired familiarity with the fine details of human anatomy?

Other health workers, too, have a part to play. Particularly in rural areas, the district nurse and health visitors could do much to bring about a more enlightened attitude to sex among the parents with whom they come into contact. But to be really helpful to the mothers they meet, they will in most cases need further preparation themselves. Having already a good background knowledge, it should be fairly easy for them to extend their understanding. In the future this extra field should be part of their training; for the present, special short courses should be arranged.

The question now arises: Suppose that all these different categories of people *do* attend special courses of instruction—will that guarantee their suitability to play a part in sex education? The answer, I suggest, is quite clearly 'No'. He who would undertake sex education with success needs many qualities which may bear little or no relation to special training or academic attainment. The first essential is personal sex adjustment and an absence equally of prudish disinclination to discuss sex and prurient tendency to discuss it to excess. In all education the teacher needs a sympathetic understanding of the pupils, but this applies with special force in sex education. Hypocrisy and narrow-mindedness are fatal. Honesty and tolerance are essential. Imagination is needed too—the ability to sympathize with the feelings of a child and to understand the perplexity of the adolescent, while yet retaining the mature judgment and emotional stability of the adult. One other quality I would add—that of a sense of humour. I know no solvent of strain more effective than laughter, and the person who cannot throw in a joke now and then has no place in sex education.

This is both a warning and an encouragement. It is a warning against judging people's suitability for sex education by their paper qualifications, and an encouragement to those thousands of good-hearted but modest folk in the street who wish to help in sex education but have been doubtful of their ability to do so.

It is now generally agreed that sex education should not be considered as an isolated subject; and its integration with the rest of education, it seems to me, has two main aspects. One aspect is that of sex education as part of health education generally, and the other is that of sex education as part of a wider education for family life.

There, surely, is a worthwhile task in which many organizations could play an important part. Could not sex education grow into something much wider and richer if really close collaboration and coordination were achieved between all the bodies doing sex education work, the moral and socia welfare organizations, those concerned with marriage guidance and family planning, organizations dealing with heredity, eugenics and population problems those working in the field of maternal and child welfare, and so on? This is obviously a matter requiring close and critical consideration by all the organizations concerned, and I commend the suggestion to their attention.

Among other matters which are simply crying out for attention is that of research. A very considerable volume of sex education work is being carried out—and, I venture to think, with some success. But w cannot close our eyes to the fact that it is all bein done quite empirically. We have our ideas about th amount and degree of accuracy of the sex knowledge of the people we are trying to educate; but we hav no exact knowledge. We have general impression of what their attitudes to sex and sex behaviour ar —but we have no exact knowledge. We make estimates of the relative efficacies of the various technique of sex education—but again we have no exact know ledge. The securing of this exact knowledge should be high up on our list of priorities. Just how it should be carried out I am not competent to say—that would need the combined intelligence and experience of educationists, medical practitioners, psychologists, social workers, statisticians and field research workers.

People's attitudes to sex, like their attitudes to any other aspect of human life, do not crystallize in isolation, but are shaped and impregnated by the views of their fellow-citizens and by the whole structure of the society in which they live. That is why some enthusiasts for sex education live in a fool's paradise. Imagining that it is possible in a few lectures to overcome the influence of years of living in a society with distorted views of sex, they are due for disillusion. The best results will follow from sex education only when the whole of our society is remodelled, and our children grow up from the earliest days surrounded by adults who feel that sex is an excellent and joyous thing in which man and woman join as equal partners, sharing benefits and responsibilities alike. Meanwhile, our scheme of sex education must not be drawn up *in vacuo*, as if sex attitudes and sex behaviour were things fixed and immutable. If it is to be really potent, it must be sex education for our particular social setting.

FAMILY FOOD CONSUMPTION IN THE UNITED STATES*

A VALUABLE report has been issued* giving a detailed account of the analysis of data obtained in the United States during a large-scale inquiry into family spending and saving, of which food consumption returns formed a part. It also includes a useful discussion of the various techniques which can be employed in collecting data and the way in which choice of method may affect the picture given by the returns.

Since the United Nations Conference on Food and Agriculture focused attention on the responsibility of a government for the standard of nutrition in the area under its control, reports which describe in detail the way in which different countries conduct dietary surveys in their own territories should find a ready welcome.

The first essential is a basic stock-taking in order to obtain an over-all picture of the food resources of the territory and the nutritional requirements of the community. This provides the background against which more detailed surveys can be tested and on which plans for betterment can be based. There are, however, many territories for which such a simple balance sheet cannot yet be prepared, because the necessary basic data are not available. Imports and exports are usually known with considerable accuracy, but acreage under food crops and the yields normally obtained are not. In some areas there is no information regarding the total number of people forming the community, far less any details of the population distribution in terms of age, sex, and occupation. Without such information nutritional work can at best be only a patchy process, and is apt to be confined to the few more fortunate individuals who happen to come under observation.

A satisfactory balance sheet does not in itself ensure that all is well. It assumes that food is being distributed according to need, and that is a thing which rarely happens. For this reason continual surveys are required in order to provide information about distribution and the factors which determine it. There is no simple way of obtaining this information, and all the methods so far employed have decided limitations. Clearly the smaller the unit that is observed, the greater the number of records which must be kept if the results are to be used as an indication of trends in the community as a whole. Yet if the unit consists of more than one individual, the possibility of maldistribution still exists.

Usually the family has been chosen as the unit for observation. Maldistribution of food may (and often does) occur inside the family; but it nevertheless represents a compact catering unit, and the individuals composing it are on the whole subject to the same controlling influences.

The present study has taken the family as the unit and it claims to represent "the entire civilian housekeeping population of the United States". The distribution inside the sample is said to check very well with census data, but all breakdowns are given in percentages, and the actual size of the sample does not appear to be stated. It would, however, have been possible to handle a very large number of budgets as no direct measurements were undertaken.

In the United Kingdom, the Ministry of Food has run a continuous "War-time Food Survey" in which the investigators have visited the families and supervised all weighings and record-keeping. Since one investigator cannot cover more than ten families at a time (visiting on alternate days during the survey week) the number of records that can be collected is limited by the number of investigators available. It is, however, a method which involves direct measurement and it also affords an opportunity of assessing the relative effects of other influencing factors.

In contrast to this, the present inquiry was conducted as follows :

"Each housekeeping consumer unit interviewed was requested to give detailed food information for the previous week as well as the information on income and expenditure for all goods and services for the calendar year 1941 and for the first quarter of 1942."

A food schedule was provided listing 177 food items, and the information sought was (*a*) food bought during the preceding seven days—quantity and price ; and (*b*) food eaten during the preceding seven days—quantity (specifying whether home-produced, bought, or other), and price. Among additional information required was "the number of meals furnished from home food supplies in the seven days covered by the food schedule for each family member, boarder, guest, or paid helper in the household".

The chief criticism against conducting an inquiry in this way is that it is too much in the nature of a memory test, and is therefore subject to all the frailties of that human mental process. The authors are not unaware of this weakness ; they themselves say :

"The method used in this study to obtain food consumption data is, of course, subject to some error. It is not expected that the homemaker can recall with great precision the exact quantities of each of the kinds of food consumed. There may be some understatement and some overstatement that is not compensated for within a single schedule. However, it is believed that in the averages for fairly large groups of families these are compensating errors, particularly for items consumed by most families."

---

* Family Food Consumption in the United States. (U.S. Department of Agriculture, Miscellaneous Publication No. 550.) Pp. vi+157. (Washington : U.S. Government Printing Office, 1944.) 20 cents.

The interpretation of the data, however, turns so much on this assumption that the errors are compensating ones that it would seem well worth while to organize a survey specially to test the truth of it. A memory test for impersonal facts might be expected to produce compensating errors; but food consumption is so closely linked with community culture and with individual likes and dislikes that the memory picture of food consumed must surely be subject to such influences and therefore liable to uncompensated errors. At present the justifiability of the assumption remains a matter of opinion.

The other major factor limiting the usefulness of this survey is the fact that it covers one season of the year only. The influence of this factor is, however, given due consideration in the discussion relating to each group of foodstuffs in turn.

On the sociological side the returns are grouped according to (1) urban, (2) rural non-farm, and (3) rural farm families, and then further subdivided according to income class. Differences were found, and these differences (in the records) are real, whatever the causes of them may be. As usual, improvement in dietary went up with improvement in income-level inside each main group and, as might have been expected, the biggest differences in the 'consumption patterns' were between the farm families and the urban ones. The rural non-farm families occupied an intermediate position. The authors point out that:

"Farm families had a better opportunity than non-farm families to maintain and improve upon their usual levels of food consumption in the face of rising food costs, food shortages, and reduction in the variety of foods offered for sale because such a large share of their total food supply was obtained from the farm."

It was found that 90 per cent of the milk, 95 per cent of the eggs, 60 per cent of the meat, poultry, fish, fats and oils, 25 per cent of the sugars and sweets, and 20 per cent of the grain products consumed by farm families were produced by themselves.

In terms of nutrients, the farm families' dietaries were superior to the urban ones in calcium, protein, riboflavin and iron, equal in thiamin and vitamin A, and inferior in niacin and ascorbic acid.

The intermediate position of the rural non-farm families is considered to reflect "the ability of many of these families to produce part of their food supply at home and to buy some farm products at lower prices than families in cities", in addition to the fact that they tended to be also of intermediate standing with regard to income.

To other survey workers possibly the most interesting part of the report will be Appendix B, dealing with the methodology. Family consumption records are always complicated by meals taken out and by odd meals given to visitors. The authors point out that "the size of family from the point of view of food consumption is not merely a count of persons, but a count of meals consumed by the persons in the family". For this reason they took the total number of meals served during the week, divided by 21, and called the resulting figure "size of family". 21 was used for the divisor because it was the usual number of meals served to each person each week. Meals taken away from home were not counted. This method of breakdown ignores age, sex and activity, and results obtained by it can only be used for comparative purposes if the communities surveyed are of similar composition. In this case the non-farm groups contained fewer children and men, and the physical activity of the adults was less than in the farm groups.

Requirements were assessed in detail in terms of "equivalent nutrition units". This is a modern variation of the old man-value computation. The use of man-value scales fell into disrepute because they were based on calorie needs only, and disregarded the fact that the requirements for other nutrients do not run parallel. Relative units can, however, be quickly calculated for any set of recommended allowances. In this study "the scales of relatives have been derived from the daily allowances for calories and the specific nutrients recommended by the Food and Nutrition Board of the National Research Council, May 1941. The dietary needs of the moderately active man were considered equal to one nutrition unit; the needs of the other sex-age-activity groups are expressed in relation to those of the moderately active man". Thus a girl of 13–15 years of age counts as 0·93 of a man unit for calories, 1·62 for calcium, 0·74 for riboflavin, and so on.

An alternative method of assessment is that which finds the requirements of the community by adding together the requirements of each sub-group and then divides the resultant totals by the total number of persons. This gives weighted requirements *per capita* and was the method used in the report, "Food Consumption Levels in the United States, Canada, and the United Kingdom".

In the present report, the data have been arranged and re-arranged in many different ways (there are forty-five very detailed tables), and in fairness it must be said that the authors do seem to have directed attention to all possible sources of error and to the limitations imposed by the methods they adopted. This is an attitude of mind that should be encouraged.

M. W. GRANT.

OBITUARIES

Mr. E. Lancaster-Jones

THE death occurred on September 9 after a short illness of Ernest Lancaster-Jones, keeper of the Science Library. He was born at Radcliffe on November 8, 1891, and was educated at Bury Grammar School. Later, with a mathematical scholarship, he proceeded to Christ's College, Cambridge, and graduated in 1914.

In 1915 he was commissioned in the East Lancashire Regiment, transferring in the following year to the Royal Engineers, with which corps he served for three years in Greece, Macedonia and Egypt. In 1916 he married Geraldine Hilda Anne Farnham, of Burnham-on-Sea, who died in 1942.

In 1920 Lancaster-Jones was appointed assistant at the Science Museum, where he performed valuable work assembling and developing the collections of acoustical and electrical instruments, on geodesy and surveying, and was responsible for the Museum handbook on the geodesy and surveying collections, which appeared in 1925. The introduction from Budapest to Britain in 1920 of the first Eötvos torsion balance provided a unique opportunity for studying the gravitational method of applied geophysics, and Lancaster-Jones devoted himself wholeheartedly to the development of this subject. Frequently, investigations could only be made during the night, and often under very difficult and trying weather conditions, but his determination and outstanding ability enabled him to devise new methods and instruments, and he soon acquired an international reputation.

Lancaster-Jones was transferred to the Science Library, where he was appointed keeper in 1938. He was largely responsible for the rapid development of the Library, enabling it to contribute so effectively owards the scientific war effort of the country. He possessed a wide knowledge of scientific literature, coupled with a natural organizing ability and an unusual capacity for work. During recent years he found additional interest in the activities of the Association of Special Libraries and Information Bureaux, and played a major part in the introduction of microfilm methods into Great Britain.

'L. J.', as he was affectionately called, was greatly espected by all who knew him. A man free of all conceit and pretences, he was completely sincere and unassuming. He was a deep thinker and a hrewd judge of human character, and successfully combined firmness and discipline with ease and friendliness. His love of various kinds of sport was nly equalled by his fondness for children. Early last year he married Eleanor Joyce Chapman of London, and with her and his son and daughter we mourn the loss of a sincere and valued friend who had so endeared himself to us.

H. SHAW.

WE regret to announce the following deaths:

Prof. W. B. Cannon, C.B., For.Mem.R.S., emeritus professor of physiology in Harvard Medical School, on October 2, aged seventy-three.

Prof. Roscoe G. Dickinson, professor of chemistry at the California Institute of Technology, known for his work on the X-ray analysis of crystals, photochemistry and reaction kinetics, on July 13, aged fifty-one.

Sir David Milne-Watson, Bart., recently governor of the Gas Light and Coke Company, on October 3, aged seventy-six.

Dr. J. C. Mottram, director of the Research Laboratory, Mount Vernon Hospital, Northwood, Middlesex, on October 4, aged sixty-five.

Mr. H. M. Pendlebury, of the Museums Department, Kuala Lumpur, on September 22, from the effects of three and a half years' captivity in Japanese hands.

Prof. J. Strong, O.B.E., emeritus professor of education in the University of Leeds, on October 7, aged seventy-seven.

NEWS and VIEWS

Prof. G. B. Jeffery, F.R.S.

DR. GEORGE BARKER JEFFERY, the new director of the Institute of Education, University of London, was associated with University College, London, from 1909 onwards, as an undergraduate, a lecturer in the Department of Applied Mathematics, and for twenty-one years as Astor professor and head f the Department of Pure Mathematics. He broke the continuity of this long service with a year t the London Day Training College (now the Institute of Education) and two years as professor of mathematics at King's College, London. His many aluable contributions to mathematical journals deal mainly with the applications of pure mathematics to hysical problems, in particular Einstein's relativity theory. As Astor professor he set himself to evelop a school of pure mathematics in London and took a leading part in the activities of the London Mathematical Society. He has figured prominently in the affairs of University College. As pro-provost of the section of the College in evacuation at Bangor, his diplomacy at the outset paved the way for a happy co-operation. Taking a keen interest in student life, he laboured to preserve the traditions of the College and to weld the students into a cororate whole. On returning to London in 1944, he took the lead in instituting student hostels. A member of the Senate of the University of London, he has taken a wide interest in educational problems, the schools as chairman of the Matriculation and Schools Examinations Council, in the University as member of the Academic and External Councils and as dean of the Faculty of Science. He has ways urged the claims of women to equal educational opportunities, especially in the London medical hools. His flair for clear thinking has steered many fficult matters through University channels.

Astor Chair of Mathematics, University of London: Prof. H. Davenport, F.R.S.

PROF. HAROLD DAVENPORT has been appointed to the Astor chair of mathematics in the University of London in succession to Prof. G. B. Jeffery and is beginning his duties at University College this session. He comes from Accrington Grammar School, the University of Manchester and Trinity College, Cambridge, of which he was formerly a fellow. He is a fellow of the Royal Society and was recently professor of mathematics in the University College of North Wales, Bangor. He has established his position as one of the most distinguished of the younger English mathematicians. His researches have been specially in the field of the analytic theory of numbers in the tradition of Hardy and Littlewood, whose pupil he was. His appointment represents a notable addition to the strength of the mathematical professoriate in the University of London, and is peculiarly happy in view of the close association of University College, London, with the University College of North Wales during the first five years of the War.

Dr. C. Ainsworth Mitchell and *The Analyst*

DR. C. AINSWORTH MITCHELL, who has been editor of *The Analyst* since 1920, has just retired from this position but retains his connexion with the Society of Public Analysts and Other Analytical Chemists in the capacity of honorary librarian. During the twenty-five years of his editorship, the scope and reputation of *The Analyst* have steadily increased, and it is largely through his exertions that it has attained its present high place among scientific journals and has become recognized as the most comprehensive record of current analytical work in chemistry throughout the world. In fact, the sales to non-members now greatly exceed in number the membership of the Society itself. Dr. Mitchell became a member of the Society of Public Analysts in 1894 and was co-editor with Dr. Bernard Dyer of the jubilee volume, which gave a most interesting account of the progress of the Society from its foundation in 1875. Dr. Mitchell is well known for his work on oils and fats, on vinegar manufacture, and particularly on the chemistry of writing inks and materials, and is the author of much original work in these fields of applied chemistry. His knowledge and experience in the examination of manuscripts and documents have been of service to the courts on many occasions, and his close association with the forensic world was recognized by his election in 1935 as president of the Medico-Legal Society. He is succeeded as editor by Mr. J. H. Lane, who has been assistant editor since 1936.

Australian Council for Scientific and Industrial Research: Retirement of Mr. Gerald Lightfoot

MR. GERALD LIGHTFOOT has retired from the post of secretary to the Australian Council for Scientific and Industrial Research. Mr. Lightfoot has been associated with the Council since its inception, and has played an important part both in the building up and in the running of what is now a great and very effective organization. Mr. Lightfoot has had varied experience; he took a first class in the Mathematical Tripos at Cambridge in 1898 and was called to the Bar at Middle Temple in 1902. A few years later he went to Australia and joined the Commonwealth Public Service, and in 1920 was appointed chief executive officer of the Commonwealth Institute of Science and Industry. When this body was reconstituted in 1926 as the Council for Scientific and Industrial Research, he was appointed secretary, and he held this position until his retirement. He reported to the Commonwealth Government on the work and organization of scientific research institutions in Great Britain and the United States, and in 1937 he visited North America, Great Britain and Europe in connexion with an extension of the Council's activities. Much of the information gained on this visit was used in extending the Council's work to' the secondary industries and in the setting up of several new divisions before the War.

Those who have been associated with Mr. Lightfoot in his work have high admiration for his sound judgment in dealing with major affairs, for his human understanding and kindness in dealing with people, and for his unfailing attention to detail in handling the numerous minor problems which accompany administration. Fortunately, he remains a member of the Council, which will continue to have the benefit of his advice and experience. He has been succeeded as secretary by Mr. G. A. Cook.

Botanist for India at Kew

IT has been announced in *Science and Culture* (India) that Dr. Debabrata Chatterji has been appointed by the Government of India to the post of assistant for India at the Royal Botanic Gardens, Kew. Dr. Chatterji had a brilliant academic career in the Presidency College, Calcutta. After a short period of service as a lecturer in botany at Vidyasagar College, Calcutta, Dr. Chatterji went to the University of Edinburgh in 1937, where he submitted a thesis on "The Endemic Flora of India and Burma" for his doctorate (*J. & Proc. Roy. Asiatic Soc. Bengal*); in this connexion he worked at the Royal Botanic Gardens, Kew, and the British Museum. Returning to India in 1939, Dr. Chatterji took up the post of lecturer in botany at the Agricultural College, Mandalay. Owing to progress made by the Japanese, he was forced to leave Mandalay in March 1942, and from April 1942 he served as a systematic botanist in the Botanical Survey, Government of India, for about a year. Since July 1943, he has been a lecturer at Cotton College, Gauhati, Assam. In 1939, Mr. K. N. Kaul of the University of Lucknow was the first Indian appointed an assistant for India at Kew. Mr. Kaul returned to India at the end of 1944 and will now be succeeded by Dr. Chatterji.

Radar During the War

DURING recent months, much has been published in the daily Press on various aspects of the many different applications of the new technique known as radiolocation or radar; and in *Nature* of September 15, Sir Robert Watson-Watt gave a comprehensive account of the manner in which radar had grown from a classical scientific experiment into a wide series of ramifications developed under the intensive pressure of war. H.M. Stationery Office has now published a pamphlet entitled "Radar—a Report on Science at War" (price 1*s.* net), which is a reprint of an official report issued by the United States Information Service. After briefly surveying the early history of radar both in Great Britain and in the United States, the pamphlet gives an interesting account in general, non-technical language of the important and very interesting part which radar in its various applications played at different stages of the world war. Although the U.S. Naval Research Laboratory and later the U.S. Army were conducting experiments in the reflexion of radio waves from ships and aircraft from the year 1930 onwards, British radar is credited with having been developed at a faster pace from 1935 under the immediate threat to Britain's security. Before the United States entered the War, however, the efforts of American and British laboratories were combined as the result of an agreement between the two Governments in 1940 and the visit of a British Technical Mission to Washington in September of that year. From that time onwards, the combined efforts of the two nations in research and development, training of personnel, and the operational use of this new weapon at sea, on land and in the air make a fascinating story. The concluding section, on "Radar in the Peacetime World", refers to the effect which the spectacular advances in radio technique made during the war years will have on the future of television and in improving the safety of travel by sea and air The number of men who have been trained in radio and radar techniques and maintenance is enormous and many of these will turn their attention to the extended application of electronics in all directions in a manner which is likely to have a profound and far reaching effect on our daily life.

Education in International Morality

THE inaugural meeting of the United Nations Fellowship was held on September 27, when Prof. R. A. Tsanoff, of the American Army University Centre, Shrivenham, Berks, and professor of philosophy in the Rice Institute, Houston, Texas, opened a discussion on "The Problems of Education in

International Morality". Prof. Tsanoff stated that ethics is pre-eminently concerned with the expanding universe of moral ideas, especially of duties and obligations. The lack of correlation—and consequent lack of adjustment—between the scientific and technological and the political worlds has been, in the main, responsible for the disharmony of war. The basic world lesson of the recent conflict, and of the stupendous part played in it by science and technology, points once again the warning finger, that mankind ignores the political implementing of a scientific age at his peril. A global age demands a global politics. The conciliation of, and co-operation between, nations is not merely good ethics; it is the very condition of survival. Neither is a mere truce between the Great Powers enough; they must learn to think in terms of the unity which unites rather than of any disunity which might separate. The recognition of the underlying unity of civilization demands a revolution in the moral and educational outlook—the correction of the 'national political' to the 'global political' outlook. Some countries will have further to go than others to reach this, and, in practice, the change-over will not be easy, for the scarcely dormant and deeply rooted subconscious prejudices of preceding ages will be a constant drag on progress.

The next meeting of the United Nations Fellowship will be held at 29 Gordon Square, London, W.C.1, on October 15, when Prof. Norman Bentwich, professor of international relations, University of Jerusalem, will speak on "The Educational and Cultural Organization of the United Nations". The honorary secretary of the Fellowship is Captain O. H. Cooke, 12 Woodlands, North Harrow, Middlesex.

German Military Maps

A collection of German military maps is on public exhibition during this month at the Royal Geographical Society's House at the corner of Kensington Gore and Exhibition Road. A few of these maps are shown on wall panels: the remainder can be seen in the Map Room on request. These maps are of interest in connexion with German plans for the invasion of England. Those shown on the wall panels include a plan of London on the scale of 1/20,000, emphasizing, in colour and by symbols, buildings and areas of special importance; for example: government offices; main railway stations, marshalling yards, tracks, and bridges; hospitals, industrial sites, and post offices; scientific institutions and historic buildings. A numbered key in the margin gives identifications and brief particulars. There are similar plans on a large scale (1/10,000) of Birmingham, Cardiff and South Shields. A night-flying target map of London, 1/100,000, is also displayed; target areas, outlined in red, include docks, airfields, reservoirs, etc. Other exhibits are a sheet of the *Stellungskarte* of Great Britain, about 2½ inches to the mile, with military information; a sheet, London (West), of the air edition of the German Army map, 1/200,000, with airfields conspicuously marked, and a sheet, Tipperary, of a 1/100,000 map of Ireland. Most of these maps are reproductions on slightly different scales, with additional information overprinted, of maps published by the Ordnance Survey. Official surveys of most countries in Europe were also reproduced by the German Staff, for example, Spain, Portugal, Turkey, Greece and Russia, and representative sheets of these are exhibited.

Announcements

Lieut.-Colonel L. P. Kirwan has been appointed secretary of the Royal Geographical Society in succession to the late Mr. A. R. Hinks. Colonel Kirwan was engaged before the War on archæological and anthropological work, including much work in the field in Egypt, the Sudan, Arabia and England, and for the last three years has been employed on the joint staff in the offices of the War Cabinet.

Prof. Bengt Edlén, of the University of Lund, will deliver a lecture before the Physical Society on "The Spectral Structure of the Inert Gases" on October 19. The lecture will be given in the rooms of the Royal Society; fellows of the Royal Astronomical Society are also invited.

Dr. A. M. Ward has been appointed principal of the Sir John Cass Technical Institute, London, E.C.3, in succession to Mr. George Patchin, who will retire at the end of the present year. The Institute has arranged full-time day classes in chemistry, physics and mathematics for the London B.Sc. degree.

The U.S. Typhus Commission Medal has been awarded to Dr. Francis G. Blake, dean of Yale University School of Medicine, and Dr. Kenneth F. Maxcy, professor of epidemiology at Johns Hopkins School of Hygiene and Public Health, for "exceptionally meritorious service". Dr. Blake initiated and directed investigations of classical importance on the clinical features and prevention of scrub typhus. Dr. Maxcy was commended for "his observations made in the field under difficult campaign conditions, which clarified earlier knowledge of the conditions under which this disease occurs and added greatly to information about the special conditions which were making this disease a health hazard of paramount importance to American troops".

The U.S. War Department states that the Secretary of War has approved a project whereby certain outstanding German men of science and technicians are being taken to the United States to ensure that full advantage be taken of significant developments deemed vital to American national security. The individuals selected have volunteered to go to the United States and have been chosen from fields where German progress is of significant importance and in which these specialists have played a dominant part. Throughout their temporary stay in the United States they will be under the supervision of the War Department.

The following promotions and transfers in the Colonial Service have recently been made: A. G. Beattie (deputy director of agriculture, Nigeria), to be director of agriculture, Nigeria; C. W. L. Fishlock (agricultural officer, Uganda), to be senior agricultural officer, Uganda; H. D. Huggins (agricultural economist, British Guiana), to be agricultural economist, Jamaica; W. T. O. Maidment (agricultural officer, Uganda), to be senior agricultural officer, Uganda; F. R. Sanders (agricultural officer, Tanganyika), to be senior agricultural officer, Tanganyika; C. E. Duff (assistant conservator of forests, Northern Rhodesia), to be senior assistant conservator of forests, Northern Rhodesia; C. Swabey (conservator of forests, Jamaica), to be conservator of forests, British Guiana; W. Pulfrey (geologist, Kenya), to be senior geologist, Kenya; F. E. Tavener (assistant director of surveys, Nigeria), to be director of surveys, Uganda.

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Detection of Birds by Radar

PERMISSION has now been obtained to publish the fact that birds can reflect radio waves with sufficient strength to be detected by radar sets. Evidence of this was given to us in the summer of 1941 by Dr. E. S. Shire, then developing centimetric radar equipment at the Air Defence Research and Development Establishment, Ministry of Supply. Confirmation was obtained by G. C. Varley in September 1941, when echoes observed on an operational centimetric set at Dover were established by visual checks to come from gannets (*Sula bassana*) flying singly above the sea. The facts were published in a secret report of the Army Operational Research Group, Ministry of Supply, in April 1942. Much fuller details, with numerous further records, were published in a secret report dated February 1945.

Since 1941, there have been numerous well-authenticated records of birds being detected by radar, first from England, then from Malta and Gibraltar, and later from New Zealand and the United States of America[1]. Indeed, with the introduction of higher powered transmitters late in 1943, bird echoes became such a menace on British coast-watching equipment that we specially trained radar operators to distinguish them from echoes of operational importance. Confusion has occurred with aircraft; but the latter are usually quickly differentiated by their greater speed. More serious is the possibility of confusion with fast-moving ships. Birds not infrequently travel with a ground-speed similar to that of a fast-moving ship, and at long range the echo from a bird flying fully in the beam of a radar set can be equal in strength to that from a ship which is below the lowest maximum of the vertical polar diagram. Birds have given rise to several E-boat scares and to at least one invasion alarm.

That birds give radar echoes is not surprising when it is realized that heavy rain is also detected. Single birds may give echoes not much smaller than those from metal spheres of comparable size. The species involved have been mainly the larger sea and shore birds, such as gulls (*Larus* spp.) and grey geese (*Anser* spp.). However, when in flocks even birds so small as a starling (*Sturnus vulgaris*) have produced echoes large enough to be a nuisance to radar operators. Experimental proof that birds can produce radar echoes was obtained by Major J. A. Ramsay of Coast and Anti-Aircraft Experimental Establishment, when he suspended a herring gull (*Larus argentatus*) from a captive balloon in such a way that the echo from the bird was clearly separable from that given by the balloon.

As yet, the radar results have produced little of ornithological interest except to show how frequently birds fly at night over the sea. However, the radar stations concerned have rarely been allowed to follow bird tracks once their identity has been established. There are two other serious difficulties: first, that of getting visual confirmation of the source of the echo, and secondly, that of following a bird track continuously on a coastal radar set owing to marked variations in signal-strength, including complete fading, due to the bird passing through successive maxima and minima of the vertical polar diagram.

On January 12, 1945, a long track was obtained on birds which later crossed the East Anglian coast near a Royal Observer Corps post, where they were identified as grey geese from their calls. (The pink-footed goose, *Anser brachyrhynchus*, is much the commonest species of goose in the area concerned.) One R.A.F. radar station plotted the birds for fifty-seven land miles, which the birds covered in 99 minutes, giving a ground speed of 35 m.p.h. Adding the plot from a neighbouring station, they covered another 22 miles in 40 minutes (33 m.p.h.). They were travelling on a bearing of 287° at an approximate height of 5,000 ft. The Air Ministry Meteorological Office state that at the time in question the wind at this height was probably about 40 m.p.h. from 070°. If this wind speed is correct, the geese were travelling with an air speed of about 25 m.p.h., which seems rather slow. This record constitutes much the longest timed track so far available for any bird in flight.

Autotrophic Flagellates as the Major Constituent of the Oceanic Phytoplankton

ALL plankton surveys record the catches of diatoms and often of peridinians, but as a rule little mention is made of the autotrophic flagellates, though it appears quite possible that they make up the greatest proportion of the oceanic vegetation; being very minute they mostly pass through the finest silk nets. Their importance has been pointed out by Gross[1], who, however, supposes their mass to be much less than that of the diatoms and peridinians.

In 1919, Allen[2] published a fundamental observation, that culture methods gave far higher counts for plankton organisms than did either netting or centrifuging. Since then, the mass of plant material in the annual crop has been calculated from the consumption of carbon dioxide and of phosphate[3] and in addition of nitrate, and silicate[4]. These estimations gave 1,200–1,600 tons wet weight per sq. kilometre for the English Channel for all but silicate. The silica consumption gave only 110 tons, and diatoms alone take up silica. It was supposed that the low figure for silica was due to its being dissolved and used over again several times. This process would have to be relatively rapid, as the phosphate is all used up in the spring, mostly in a few weeks. In fact, however, the siliceous test of the diatoms is extraordinarily insoluble. Diatoms, with their fine markings perfect, are dredged from the ocean depths and are recognizable in geological deposits; they are of much importance in identifying oil-bearing strata. Miss F. A. Stanbury and I have tried to dissolve diatom tests in alkaline solutions, from the alkalinity of sea-water upwards to pH 11, both at air temperature and at about 100° C.; we have not succeeded, even with trials of long duration. Furthermore, Coupin[5] showed that diatoms get the substance of their siliceous valves from the silica of silicates of aluminium, not from vitreous or gelatinous silica.

Again, measurements of the light-extinction coefficient of sea-water indicate that it is everywhere much greater than that of distilled water. The difference appears to be due to a suspension of very finely divided mineral matter; this dissolves slowly, and so the silica removed by diatoms is restored, as it is also by the upwelling of the bottom water due to thermal circulation or impact against oceanic banks. Diatom valves may disappear, but Hart[6] has shown that this is due to their fragmentation in the gut of Crustacea, such as *Euphausia superba*.

All these observations are entirely in accord with the view that autotrophic flagellates and peridinians together constitute by far the larger portion of the oceanic phytoplankton. As the peridinians are usually less abundant than the diatoms, the bulk of the productivity may well be accounted for by the flagellates.

Occurrence of the Diphyllobothriidæ in Ireland

INTEREST in the Diphyllobothriidæ has been aroused by the reported occurrence of plerocercoids in the trout of reservoirs in South Wales[1], in Poulaphouca near Dublin[2], and in Northamptonshire[3]. A general survey of these outbreaks has been given by Lapage[4]. In the Dublin outbreak two species of *Diphyllobothrium* are involved. One of these, which has as definitive hosts three species of gulls, was identified by Baylis[5] as *D. dendriticum* (Nitzsch, 1824) and was considered by him to be identical with the South Wales parasite. The other species, of which the adults were found in cormorants and shags, have been identified tentatively by Dr. Baylis (personal communication) as *D. ditremum* (Creplin, 1825). The separation of the plerocercoids of these two species has not yet been effected.

A third species, *D. latum* (Linn., 1758), has for long been known to occur in Ireland. The species was first recorded from man in Ireland by Bellingham[6]. A number of modern cases have been published, all from patients in the County Leitrim area[7]. Dr. T. V. McLoughlin kindly sent a further specimen of *D. latum* to us. This specimen was obtained in October 1944 from a boy aged fourteen, who gave a history of occasionally eating perch from Gardice Lake, Co. Leitrim. Accordingly it was considered desirable to examine fish from this district.

Perch were obtained from Gardice Lake and from he first half-mile of a canal which passes through this Lake and joins it with a number of other lakes in the vicinity.

Seventy-nine perch were examined, and of these hirty-five were infected with plerocercoids. The fish varied from 9·5 to 24·7 cm. in length, sixty-one ranged from 10 to 15 cm. and sixteen from 15 to 20 cm. The findings for these two groups are given in Table 1.

TABLE 1.

No. of plerocercoids per fish	Nil	1	2	3	4	5	6	7	8	
No of fish in Group 1 10–15 cm. in length	40	14	5	2	–	–	–	–	–	61 fish examined
No of fish in Group 2 15–20 cm. in length	4	4	2	2	1	1	–	1	1	16 fish examined

Two of the fish examined are not included in the table; one of these, 9·5 cm. in length, contained no plerocercoids, and the other, 24·7 cm. in length, contained thirteen plerocercoids. Similar plerocercoids were found in each of two perch obtained from Lough Allen on the River Shannon, Co. Leitrim.

Plerocercoids from the Gardice Lake perch were used in the following experiment. Two adult dogs were fed, one with eight and one with two plerocercoids. In the fæces of the dog which had received eight plerocercoids *Diphyllobothrium* ova were present sixteen days later. This animal continued to pass ova for four weeks. The worms were then passed spontaneously. Ova were found in the fæces of the second dog twenty-seven days after feeding. This animal was given an anthelminthic eighty-two days after feeding and two specimens of *D. latum* were obtained. We are indebted to Dr. H. A. Baylis for examining one of these.

A superficial comparison between the *D. latum* plerocercoids and the plerocercoids obtained at Poulaphouca Reservoir, Dublin, is of interest as several morphological and ecological differences were observed.

The *D. latum* plerocercoids were opaque and had a dull white appearance. Living specimens were only sluggishly motile and seldom relaxed sufficiently to lose their typical irregular, deeply wrinkled appearance. When killed in tap water, the scolices usually remained invaginated and the deep wrinkles, in varying intensities, were always present. Of the eighty-one plerocercoids located in the fish from Gardice Lake, seventy-one were found in the skeletal muscles and only ten in the peritoneal cavity or abdominal viscera. On section, no inflammatory reaction was observed in the surrounding tissue.

Plerocercoids from the fish of Poulaphouca Reservoir are rather translucent and have a glistening white appearance. When living they are actively motile and except when strongly contracted deep wrinkling is not apparent. They invariably relax when killed in tap water, their scolices evaginate and assume a lanceolate or almond-shaped appearance, and wrinkles are never present although some specimens show segmentation. Two plerocercoids were found in the skeletal muscles of one out of one hundred and ninety-eight infected trout examined to date from Poulaphouca Reservoir. Otherwise the infection in these fish was confined to the viscera and subserous tissues of the abdominal cavity; an inflammatory mass of blood-stained granulation tissue was frequently present.

Fish from some Irish waters other than those mentioned above were examined. In the following localities plerocercoids, which superficially appeared similar to those from Poulaphouca Reservoir, were found in trout (*Salmo trutta*), salmon (*S. salar*) and char (*Salvelinus colii*).

TABLE 2.

County	Habitat	No. of fish examined	No. of fish infected	Remarks
Wicklow	Reservoir	14 brown trout	13	Fish 19–31·7 cm. in length. Plerocercoids present varied from 2 to more than 200 per fish
Dublin	,,	17 brown trout	1	Single infected fish 63 cm. in length had 3 plerocercoids
Mayo	Lough Mask	8 brown trout	2	Fish 30·5–35·7 cm. Those infected contained 32 and 10 plerocercoids respectively
Galway	Four lakes in Connemara	25 brown trout	2	Two infected brown trout, 35 and 36·7 cm., had 3 and more than 100 plerocercoids. Uninfected fish were less than 15 cm. in length.
,,	,,	20 sea trout	6	Sea trout, 22·3–41·3 cm. Only one or two plerocercoids in each fish
,,	One of these lakes	3 salmon	1	Infected salmon, contained two plerocercoids
Donegal	Lough Eak	3 char	3	Each char contained more than 50 plerocercoids

Mortality owing to the presence of the parasites was not recorded in any fish other than those from the Poulaphouca Reservoir.

Periodate Oxidation of Sugars in Neutral Phosphate Buffer

WHEN yeast mannan was oxidized with sodium periodate in phosphate buffers of various pH values, it was discovered that the amount of oxygen consumed during the oxidation is enormously increased when the pH of the solution is raised above 4–5. At $p\text{H} = 7$, the consumption of oxygen is about ten times as large as at $p\text{H} = 3$[1]. It was shown that two thirds of the mannan molecule is oxidized to carbon dioxide at $p\text{H} = 7$ and 50°. The reaction seems to be catalysed by phosphates, for the velocity of oxidation is much lower in an acetate buffer of $p\text{H} = 5{\cdot}3$ than in a phosphate buffer of the same pH.

A number of sugars and similar compounds have been oxidized in the same way by sodium periodate in a phosphate buffer of $p\text{H} = 7{\cdot}0$ at 50°. The concentration of periodate in the solution was about 0·05 m. The amount of periodate consumed was determined by iodometric titration in an excess of the same phosphate buffer. At this pH, iodate does not react with potassium iodide, and each mole of periodate will liberate only two atoms of iodine. The time required for complete oxidation was 12–15 hours except in the case of α-glycerophosphate, which was oxidized very slowly. The accompanying table gives the end values of oxygen consumption in these experiments compared to the results found by other investigators in strongly acid solution.

Substance	Phosphate buffer $p\text{H} = 7{\cdot}0$	Strongly acid solution	
	Atoms of O per mole	Atoms of O per mole	Found by
Xylose	4·4	4	Khouvine, Arragon[1]
Glucose	5·2	5	Fleury, Lange[2]
Mannose	5·2	5	Fleury, Lange[2]
Fructose	5·3	5	Khouvine, Arragon[1]
Mannitol	5·2	5	Malaprade[4]
α-glycerophosphate (sodium salt)	5·9	1	Fleury, Paris[5]
α-methyl glucoside	10·1	2	Héri sey, Fleury, Joly[6]
Glucose-*l*-phosphate (potassium salt)	8 8	2 (theoretical)	Not investigated
Maltose	18·1	10*	Ahlborg[7]
Trehalose	19·6	4	Jackson, Hudson[8]

* At $p\text{H} = 3$, maltose consumes only 4 atoms of O per mol (Ahlborg, not published).

A preliminary investigation showed that other disaccharides (sucrose, lactose, melibiose) also consume 16–19 atoms of oxygen per mole when oxidized under the same conditions.

The following conclusions may be drawn from the experiments:

(1) Monosaccharides and polyalcohols, the carbon chain of which is broken completely by periodate oxidation in acid solution, are oxidized in the same way in a neutral buffer.

(2) If a mono-, di- or poly-aldehyde containing hydroxyl groups is formed by acid periodate oxidation, much more oxygen will be consumed in neutra than in acid solution, and the bulk of the molecule is oxidized to carbon dioxide. Probably the 'normal oxidation first takes place, yielding formic acid, formaldehyde and the oxaldehyde, which is ther broken down completely.

The Warburg method was employed to measure the amount of carbon dioxide liberated during the oxidation. One of the side bulbs of the Warburg flasks contained 0·1 m. $NaIO_4$ solution and the othe 4 N H_2SO_4. The oxidation was started by tipping the periodate into the solution. When no mor carbon dioxide was evolved, the acid was added from the other side bulb to expel all carbon dioxide from the solution. The following results were obtained

Substance	Moles of CO_2 per mole	Temperature
α-glycerophosphate (sodium salt)	2·0	50°
α-methyl glucoside	3·8	40°
Glucose-*l*-phosphate (potassium salt)	3·7	40°

The complete course of this new type of periodat oxidation cannot be accounted for as yet. Probabl there are also other oxidation products in addition t formaldehyde, formic acid and carbon dioxide. Eve in acid solutions the same reaction may be observed as a secondary reaction, at least when the temperature is raised to 40°–50°. That will explain wh some investigators have found that the periodate consumption increases slowly all the time and never comes to a standstill.

Influence of Vitamin E on the Utilization of Carotene from Oils

IN a previous communication[1], it was indicated that the variations in growth response of vitamin A-deficient rats to carotene dissolved in different oils may be due to the difference in vitamin E contents of the oils. The effect of equalizing the level of tocopherol in the supplements has since been studied and the results found to support the explanation.

Young rats were depleted of vitamin A reserves on a diet consisting of 68 per cent sucrose, 18 per cent extracted casein, 10 per cent brewers' yeast and [illegible] per cent Osborne and Mendel salt mixture, and supplemented with 1 µgm. of calciferol a week. When symptoms of deficiency were observed, the rats were divided into groups and given the supplements of carotene and tocopherol, six days in the week, as stated in the accompanying table. The fæces of the rats were collected for fifteen days, and the excreted carotene determined by the method of Ramasarma and Hakim[2].

The vitamin E contents of the groundnut, olive and coco-nut oils used in the experiment, determined by a modification of Moore's procedure[3], were 386, 175 and 0 µgm. per gm. respectively. It may be seen that the total vitamin E ingested by rats in groups *G*, *O* 2 and *C* 3 was practically the same, namely, [illegible]8·6 µgm. daily, as also in groups *O* 1 and *C* 2, namely, [illegible]7·5 µgm. daily.

Group	No. of rats	Supplements	Gain in wt.		Carotene excreted %
			3 weeks (gm.)	5 weeks (gm.)	
G	6	1 µgm. carotene in 100 mgm. groundnut oil	16	22	7
O 1	6	1 µgm. carotene in 100 mgm. olive oil	12	16	0
O 2	6	1 µgm. carotene and 21·1 µgm. α-tocopherol in 100 mgm. olive oil	14	20	0
O 1	5	1 µgm. carotene in 100 mgm. coco-nut oil	4	7	0
C 2	6	1 µgm. carotene and 17·5 µgm. α-tocopherol in 100 mgm. coco-nut oil	9	13	0
C 3	6	1 µgm. carotene and 38·6 µgm. α-tocopherol in 100 mgm. coco-nut oil	14	17	trace

The control groups of rats given the different oils, and one group on tocopherol in coco-nut oil, declined in weight and died.

The results show that the wide variations in growth-response to 1 µgm. of β-carotene in groundnut, olive and coco-nut oils were reduced when pure α-tocopherol was added to the oils low in tocopherol, and the total intake of vitamin E thus equalized. The slight persistent difference might be due to the occurrence in the oils of other isomeric tocopherols which are more efficient antioxidants than α-tocopherol[4].

Gridgeman[5] failed to confirm the vitamin A-E synergy, but the results given above support Hickman's[6] conclusions. Experiments with other dosage levels of tocopherol are in progress.

I am grateful to Prof. V. Subrahmanyan for his keen interest in the work, and to the Lady Tata Memorial Trust for the award of a scholarship.

Frost Injury Simulating Virus Disease Symptoms on Potato Foliage

THE production of virus-free seed potatoes has been a matter of increasing interest in the British Isles during recent years. The methods of building up healthy stocks originally adopted in Ireland and now being favoured elsewhere consist, briefly, in the scientific testing of selected plants in the glasshouse and the subsequent propagation of proved healthy units in isolation in the field. Foundation stocks produced in this manner are distributed to the growers, whose crops are subject to a rigid system of inspection before being certified for seed purposes.

In the working of such a scheme, not the least difficult part is that of the potato inspector, who must diagnose virus infection in the field; and it is in this connexion that we wish to direct attention to the effects of frost on potato foliage. The majority of agriculturists are familiar with the type of injury caused by late spring frosts, such as occurred in April and May of this year; and it is probable that most potato inspectors can also recognize the after-effects of such frosts although these may not be obvious until four to six weeks after the damage has occurred. These effects have been described by Murphy and McKay in a previous publication[1]. Little appears to be known, however, regarding the possible damage to potato foliage caused by the dropping of night temperatures below freezing point during June and early July. So far as we are aware, the only previous reference to such injury is that by MacMillan[2], who describes the development of necrotic spots on the tops of potato plants due to sudden cooling at night during summer. Symptoms of this type have not been observed by us, but evidence of a circumstantial character has been accumulating which suggests that cold nights in early summer are liable to produce other effects which may be mistaken for virus disease symptoms. As in the case of late spring frosts, it would appear that these effects may show up almost immediately, or their development may be delayed until leaves which are still folded at the critical period become fully expanded. A few instances will serve to illustrate this point.

In 1929, one of us (R. McK.), in company with the late Dr. Davidson of the Department of Agriculture, inspected a crop of potatoes grown for seed purposes in a low-lying peaty field in Co. Donegal. The crop consisted of five varieties, Up-to-Date, Sharpe's Express, Kerr's Pink, King Edward and Arran Chief. These were grown in contiguous long strips of twelve drills each in the order named. A sharp frost had occurred on July 7, and when the inspection was made ten days later, the top growth of the Up-to-Date, Kerr's Pink and Arran Chief was strongly mottled and the leaflets somewhat distorted, while only an occasional plant of Sharpe's Express and King Edward showed pale blotches. The result was that at a distance of thirty yards, the location of the former varieties was clearly discernible by reason of their yellowish mottled hue. Although any individual affected plant might reasonably have been diagnosed as suffering from virus infection, the previous history of the crop, and the manner in which the symptoms developed, left no doubt that the effect was entirely due to frost. The difference in reaction of the varieties was ascribed to the fact that a dense mass of foliage was present on those which showed most mottling, while the drills of Sharpe's Express and King Edward were still open. The erect tops of the latter would therefore have been drier owing to the free circulation of air about them.

In the same year, another suggestive incident occurred in one of the Northern counties. A crop of Arran Victory grown from a special stock of certified seed was rejected on inspection because practically every plant showed mottling. Seed from the same stock planted on higher ground on a neighbouring farm produced a perfectly normal crop and was awarded a stock certificate. The inspector took the view that in the former case old seed must have been mixed with the new in order to augment the crop. The plants were seen by one of us about the middle of August, but by that time they were approaching maturity and foliage symptoms were obscured by a deposit of spray. It was noticed, however, that the field was situated in a hollow, and, suspecting frost injury, an interest was taken in the subsequent history of the stock. In the following year, a crop from the tubers of the supposedly diseased plants was absolutely free from mottle; the stock was continuously grown in isolation, and six years later its descendants were sufficiently healthy to qualify for the highest grade certificate.

In July 1944, complaints were made that certain crops of Arran Pilot potatoes grown in Ireland from certified seed showed widespread mosaic, while seed from the same stock grown in other localities produced normal plants. During the last week of June 1944, night temperatures of 35° F., 32° F. and 33° F. were registered in Dublin, while in many inland localities and in the north one or more degrees of frost occurred. Samples of the affected Arran Pilot plants were obtained by us, and the tubers taken from them were grown both in the glasshouse and out of doors this year. No disease symptoms appeared in any of the plants, and tests revealed that the only virus present was an extremely mild strain of virus X. Here again, the circumstances suggested that frost was responsible for supposedly severe virus disease symptoms.

More direct evidence of the development of mosaic mottling in potato foliage due to low temperatures was obtained this year. On March 26 a severe frost occurred which caused considerable damage out of doors. In a cold greenhouse at the Albert Agricultura College devoted to the propagation of virus-fre potato units, it was observed on April 9 that whereas the plants generally were unaffected, one small shoot of a President plant displayed a conspicuous ligh and dark green mottling of the leaves, typical o that produced by a non-necrotic strain of virus X This shoot had emerged close to the rim of the po and was about 2½ in. high when first noticed, whil the central shoots were 6–7 in. high. Having firs ascertained that the affected shoot originated fron the tuber sett, tests were made which establishe conclusively that it was not infected with any of th known mosaic viruses. Moreover, the remainder o the plant failed to show any disease symptoms u to the time of maturity, nor was it possible to demonstrate the presence of virus in its foliage. Accordingly it is believed that the mottling was an effect of lov temperature, acting on a shoot which was rendere susceptible by reason of its stage of development an location of its tip close to the soil or rim of the po just at the critical period.

Although the available evidence is mainly of circumstantial character, it is sufficiently suggestiv to warrant an investigation of frost effects in genera on potato foliage. In the meantime, potato inspector who observe wholesale mottling of crops grown fron certified seed should bear in mind the possibility o frost injury, and should endeavour to have representative plants scientifically tested before condemnin the stock. For various reasons, the cold wind-swep northern districts are those favoured for the propagation of seed potatoes, and it is just in such localitie as these that low night temperatures are most likel to prevail during the summer months.

An Arsenic-Resistant Tick

THE article "Biological Control as a Supplemen to Chemical Control of Insect Pests", by Dr. W. E Ripper in *Nature* of April 15, 1944, mentions seve species of injurious insects which have evolved race more resistant to certain insecticides than are th ordinary populations of those insects.

We have encountered this phenomenon in a arachnid, *Boophilus decoloratus* (Koch), a one-hos tick, commonly called the 'blue tick' in South Africa Resistance to arsenical dips was first noticed in th tick in 1938 at East London, South Africa, when th trouble was confined to a small area. Its sprea north and south along the coast, was rapid, and i 1940 it was clear that the arsenic-resistant tick ha established itself in the Bathurst district. This wa sufficiently close to our laboratories to allow us t make extensive experiments and observations. W are unable to recall here the long and varied serie of experiments carried out during the past five year when many thousands of ticks have been treate with many different chemicals. The results of thes experiments were often inconclusive owing to ou uncertainty of technique and also to the fact tha we were dealing with mixed populations of ticks.

In 1944 we began investigations on a new chemic which enabled us to perfect our technique. How ever, it was not until May 1945 that we obtained a sufficiently large number of ticks from a presumed 'non-resistant' area to test alongside ticks from a presumed 'resistant' area. These two gatherings of ticks arrived at our laboratories within forty-eight hours of each other, and batches of a hundred fully engorged female ticks from each locality were dipped in arsenical solutions of different concentrations. A hundred ticks from each area were treated in tap water as controls. After dipping, the ticks were dried in a manner simulating natural conditions, and they were then placed in pairs in tubes and kept in an incubator at 25° C. and 100 per cent relative humidity.

In both cases the tap water had little or no effect on laying, as 95 per cent and 93 per cent of the ticks so treated laid large batches of eggs, and hatching was also heavy.

Ticks from the presumed 'non-resistant' area responded readily to the arsenical treatments, as only 37 per cent laid after treatment in 0·16 per cent As_2O_3 (7-day dipping strength), while 0·32 per cent As_2O_3 and 0·64 per cent As_2O_3 reduced laying to 7 per cent and 1 per cent respectively. The effect of the arsenic on hatching was also apparent, as only three batches of eggs laid by ticks treated in 0·16 per cent As_2O_3 showed partial hatching. The treatment has to all intents and purposes resulted in a perfect control.

On the other hand, ticks from the presumed 'resistant' area were little affected by the arsenical washes, as laying occurred in 95 per cent, 83 per cent and 63 per cent of the ticks treated in 0·16 per cent, 0·32 per cent and 0·64 per cent As_2O_3 respectively. Hatching was also fairly heavy, as 76, 68 and 35 of the batches laid by ticks treated in 0·16 per cent, 0·32 per cent and 0·64 per cent As_2O_3 showed hatchings. In this case the treatment has resulted in a very imperfect control, even with concentrations of As_2O_3 which would injure cattle.

It is also interesting to note that the arsenical solutions produced a well-marked time-lag in egg laying, which is also further emphasized in the hatchings. This lag is so constant that it cannot be explained by experimental error.

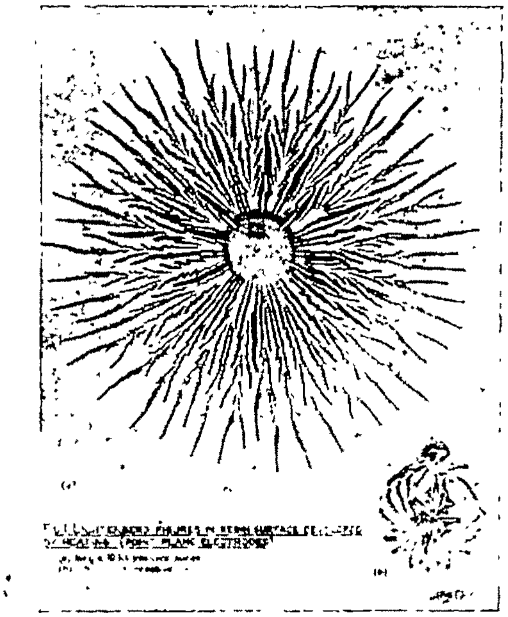
Electric Discharge on a Dielectric Surface (Lichtenberg Figures)

The following method of developing a latent Lichtenberg figure on the surface of certain types of solid dielectrics is very successful. So far, only a 'silicon' type of synthetic resin, 'Novalak' (fusible phenol formaldehyde polymer), ester gum and cumar resin have been used; but it appears necessary merely that the dielectric should be hard and brittle at ordinary temperatures and should soften quickly at some higher temperature. For example, in one experiment a piece of the resin was fused and poured on a clean glass plate to form, when cool, a hard smooth and uniform coating. This was placed between a needle point and an earthed metal plate. A single positive (or negative) voltage surge of magnitude 10 kV. was applied. No change of the surface was visible. On gently heating the resin coating, however, until the softening temperature was just reached, thread-like grooves appeared which, in a few moments, assumed the characteristic form of a Lichtenberg figure. At this instant the heating was stopped, otherwise the figure disappeared rapidly as the resin liquefied.



To photograph the figure, the coated plate was placed in a photographic enlarger, in the position normally occupied by a negative. A black disk superimposed over the image of the illuminant, formed in front of the lens, stopped all the emergent light except that differently refracted by the minute grooving. The accompanying reproduction shows the results obtained with a positive and negative surge respectively.

It is hoped to give later a detailed explanation of the mechanism; its association with bound electrostatic charges and the resultant attraction is clear.

Formation of an Addition Compound of Calcium Silicate and Sodium Fluoride

In connexion with some experiments concerning the decomposition of calcium fluoride by fusing with silica and sodium carbonate, the formation of needle-shaped crystals was observed. The crystals were analysed, and it appeared that the formula of the compound must be Ca_2SiO_4NaF, as is seen from the following data:

	% CaO	% SiO_2	% Na	% F.
Observed	51·5	28·6	11·0	8·5
Calc. for Ca_2SiO_4NaF	52·36	28·04	10·74	8·87

An X-ray investigation of the compound by the Laue, rotation, and Weissenberg methods has given the following results. The Laue symmetry is $C_{2h}-2/m$. The deviation from the symmetry $D_{2h}-mmm$ is, however, very slight. The diagonal axis is perpendicular to the direction of the fastest growth of the crystals. The dimensions of the unit cell are the following: $a = 20 \cdot 6$ A., $b = 21 \cdot 1$ A., $c = 7 \cdot 55$ A., $\beta \sim 89 \cdot 5°$. The density is 2·98. This value corresponds to 27·6, that is, 28 formula units in the unit cell. As in all photographs the reflexions from the faces $h0l$ with $h + l = 2n + 1$ and $0k0$ with $k = 2n + 1$ are missing, the space group $C_{2h}^5 - P2/c$ is probable. An investigation of the grouping of the 252 atoms in the unit cell has not been attempted.

Powder photographs of melts with the following compositions were taken:

(1) $2(2\ CaO + SiO_2) + NaF$
(2) $2\ CaO + SiO_2 + NaF$
(3) $2\ CaO + SiO_2 + 2\ NaF$
(4) $2\ CaO + SiO_2 + 3\ NaF$.

Preparation 1 showed the reflexions of Ca_2SiO_4NaF and some other lines which could not be identified. Preparation 2 showed only the reflexions of Ca_2SiO_4NaF. Preparations 3 and 4 showed the lines of Ca_2SiO_4NaF and of NaF. In all photographs the interferences belonging to the Ca_2SiO_4NaF phase were identical as regards intensity and position. Thus the stoichiometrical composition of Ca_2SiO_4NaF seems to be very well defined, and no addition compounds with the ratio NaF : Ca_2SiO_4 greater than 1 seem to exist.

I should like to thank Mr. Bengt Åman for his assistance in part of the experimental work.

Emission Bands of the Fluctuation Type in the Spectrum of Iodine

As part of an investigation undertaken in this laboratory on the emission spectra of halogens and halogen derivatives of methane[1], the emission spectrum of iodine is being studied. The spectrum is excited by a high-frequency as well as a transformer discharge in iodine vapour of pressure equivalent to the saturated vapour pressure of iodine at room temperature. A Steinheil 3-prism glass spectrograph and medium Hilger quartz and constant-deviation glass spectrographs have been used as resolving instruments. Super Panchro-press *P* 1200 and Process Regular *B* 20 Kodak plates were used.

The spectrum in all cases consists of a large number of diffuse broad bands in the region 4800–3450 A. to which, only, the present note relates. Previous investigators[2] have, however, recorded in this region only wave-lengths of the maxima of two continuous (?) bands at 4800 and 4300 A. and a weak one at 4020 A. In the present experiments the so-called continuous band at about 4800 A. is one of the eight diffuse bands which form one group. Similarly the band at about 4300 A. is one of the seven and that at 4020 A. one of the five bands in the second and third groups respectively. Between 3950 A. and the well-known continuum at 3414·3 A., we have the fourth group of such diffuse bands.

All these details are more clearly brought out on the process than on the panchromatic plates, which do not give much contrast. It is probably for this reason and also because low-dispersion instruments are generally used in this rather difficult region, particularly below 4100 A., that the details of the spectra might have escaped the attention of previous investigators. Thus, for example, the four bands observed here between 4094 and 4017 A. appear, under low dispersion, as a single band. The accompanying table gives the wave-lengths of the maxima of all the bands observed in the region 4750–3475 A. The intensities given refer to visually estimated values for the bands as obtained on the process plates, the sensitivity of which falls rapidly above 4350 A. For this reason, the intensity values of the first group of bands do not give correct information of the relative intensities of these bands. The panchromatic plates show that the bands at 4747·2 and 4662·1 A. are, along with that at 4575·6 A., the strongest in the first group.

Group	Int.	λ in air (A.)	ν vac.	Group	Int.	λ in air (A.)	ν vac.
I	0	4747·2 *B*	21059	IV	10	3944·1	25347

	2	4517·7	22129		6	3855·8	25928
	4	4471·0	22360		3	3820·1	26170
	2	4430·7	22563		4	3798·0	26322
	3	4389·4	22776		1	3770 4	26515
	8	4353·3	22965		1	3751 2	26651
					1	3739 5	26734
II	5	4316 8	23159		2	3720·1	26873
	8	4230·9	23353		2	3685·6	27118
	8	4241·8	23568		2	3668·9	27248
	6	4201·5	23794		2	3640·2	27468
	5	4155 5	24058		2	3622·8	27595
	4	4123 3	24246		2	3600·7	27764
					2	3577·4	27945
III	5	4093·5	24422		1	3535·4	28277
	5	4067·0	24581		?	3513·1	28457
	5	4044·9	24716		1	3500·1	28562
	3	4017·4	24885		1	3479 6	28731

The bands seem clearly to belong to the so-called fluctuation type of bands[3] and are probably due to a transition between two electronic states, the lower of which possesses a flat potential energy curve. The first three bands are very broad (*B*), the over-all widths being about 332, 239 and 240 cm.$^{-1}$ respectively. All the other bands which are also broad have an average width of about 115 cm.$^{-1}$. This fact probably indicates that the flat final level is common to all of them. Excepting the first three bands in group I, the average wave-number difference between successive bands in the first two groups is about 214. The same difference in bands of group III is about 154. The bands of group IV appear to occur in doublets of which six are very obvious and are shown as such in the table. The average wave-number difference of these doublets is again of the order of 158. The occurrence of these two wave-number differences ($\sim$ 214 and 154) strongly suggests that the bands are due to the diatomic molecule I_2. This and the fact that the bands occur in four distinct groups suggest that they involve more than one electronic level for their initial states, the wave-number differences between corresponding bands of successive groups being of an order of magnitude which is too big to be regarded as a vibrational frequency of the iodine molecule. Further elucidation of these bands must await the investigation on the other regions of the iodine spectrum which is in progress.

CARNEGIE INSTITUTION OF WASHINGTON

ANNUAL REPORT

YEAR BOOK No. 43 of the Carnegie Institution of Washington for 1943–44 covers the year July 1, 1943–June 30, 1944, including the reports of the executive committee, of the auditors and of the president, together with reports on departmental activities and co-operative studies, and a bibliography of publications of the Institution, November 1, 1943–October 31, 1944. The report of the president, discussing chiefly the Institution's plans for the future and the problems of transition from war to peace, points out that military research is likely to continue on a more extensive basis after the War. Recognizing the conviction that the United States must participate actively in definite efforts to maintain the peace, he points out that the world has the best opportunity possible for a long peace if the United States remains strong, and an essential ingredient is continued attention to possible military applications of science. Such military research in normal times can be more appropriately done by organizations the work of which is closer to definite application than the Institution itself.

The most important element in the Institution's planning is definition of the programmes of the several departments, and such definitions should not be so rigid as to exclude the seizure of unexpected opportunities. Dr. Vannebar Bush also emphasizes the Institution's need of men of different talents and calibre, since research is usually an affair of well-constituted teams; but mediocrity in its objectives or accomplishments cannot be tolerated. An adequate approach to the formulation of long-range programmes of research in the different departments can be made only if the aims of the Institution as a whole are clearly grasped. In view of the opportunity of the Institution for the interpretation and dissemination of scientific research, he suggests that reasonable and dignified provision for such efforts might appear in its plans. It is important to ensure that its internal policies and external relations are in sound condition for the task. He also comments on the beneficial results of relations between industrial research laboratories and those of the Institution.

The report of the Department of Astronomy refers to a reduction in the astronomical work of the Mount Wilson Observatory. The most interesting observational result of the year was the resolution of several extragalactic nebulæ among the two companions of the Andromeda nebula and the central region of the Andromeda nebula itself. For this purpose, red-sensitive photographic plates were used with a filter transmitting a very limited spectral region. The participation of the Geophysical Laboratory in the war effort continued along the same lines during the past year as described in the last two annual reports. The report includes abstracts of a few papers published in technical journals during the past year and representing previous work of the laboratory. The Department of Terrestrial Magnetism continued its analyses of cosmic data, which have continued to increase polar, geomagnetic, ionospheric and auroral correlations. The Department undertook to serve as a clearing house for observations of sunspots by American observers pending re-establishment of communications with the international centre at Zurich. Important contributions leading to improvement of the radio-communication circuits resulted from the continued operation of ionospheric recorders, and the 60-in. cyclotron was completed in December 1943. The report of this Division also includes an account of cosmic ray studies at the California Institute of Technology and of cosmic ray research at the University of Chicago.

The Division of Plant Biology continued to devote much of its effort to problems arising out of the War and, in co-operation with the College of Pharmacy of the University of California, investigated the isolation of a new antibiotic, chlorellin, which is obtained from the green unicellular alga *Chlorella*. Facilities for the culture of larger quantities of the organisms and methods for the extraction of chlorellin have been worked out, and some preliminary tests made with animals. In co-operation with the U.S. Soil Conservation Service, the staff of the Division has also undertaken a programme for the production of new range grasses, utilizing principles recently worked out in the Division. Grass stocks from many parts of the world are being employed, and in 1943 seven different cross-pollinations were made between members of two sections of the genus *Poa*; these have been augmented by twenty-four additional combinations tried under better conditions during 1944. The hybrids obtained demonstrate that remotely related species of *Poa* can be crossed successfully. Hybrids are sought that will combine hybrid vigour and greater climatic tolerance, drought and disease resistance and greater soil-holding capacity with a longer period of use for livestock. Very little field-work has been done in any of the Division's projects.

The Department of Embryology continued its studies on the physiology of reproduction in the Rhesus monkey and other animals on a small scale. The report includes brief accounts of work in human embryology, the exchange of substances between the blood and surrounding tissues, tumour studies, nutrition and the comparative anatomy of primates.

The Department of Genetics investigated the origin of resistance to penicillin in *Staphylococcus aureus* and has found that strains resistant to increasingly higher concentrations can be produced by selection, resistance apparently being acquired through mutation. X-ray experiments with *Penicillium notatum* have shown that morphologically detectable mutants can readily be induced, and the frequency of mutants increases with the dosage, reaching 45 per cent at 100,000 roentgens. Studies of mutation in bacteriophages showed that radiation causes a marked delay in their reproduction. A study of the genetics, taxonomy and ecology of flies related to *Drosophila pseudoobscura*, representing a two-year period, is included, and is chiefly concerned with clarifying the concept of biological race and with methodology of racial studies. Investigations on the incidence of spontaneous mouse leukæmia confirm that the role of longevity is far more complex than had been supposed and appears to depend on numerous variables, both genetic and non-genetic. Polyploidy investigations recorded concerned the Russian dandelion and hemp; where, as a war emergency project, an attempt has been made to produce a strain of fibre hemp with reduced marihuana content. Endocrine studies on doves and pigeons have shown that the development of endosteal bone following dosage with œstrogenic hormone occurs in the absence of the parathyroid glands, and the evidence indicates that it is probable that most of the 'bound' calcium is attached to the phosphoprotein, serum vitellin. The Nutrition

Laboratory continued to be concerned mainly with war research projects, carried out a special investigation on the metabolism of diabetes mellitus, and made a study of physiological clinical interest on the breathing pattern and rate of air flow in asthmatic patients. Special projects in the biological series also reported include the results of studies on Diatomaceæ, embryology, embryological pathology and reproductive physiology, the maintenance of a *Drosophila* stock centre in connexion with investigations on the constitution of the germinal material in relation to heredity, and the influence of nutrition on the chemical composition of the normal body.

THE BRITISH PIG-RAISING INDUSTRY

As a part of farming which has had very low priority during the war years, pig production shows clearly some of the major problems confronting the British livestock industry. The scope and form of development must depend upon the broad framework of policy as laid down by the State; yet a policy as a whole is often difficult to break down into terms applicable to individual farms and herds. Throughout the discussions on pig production at the meeting on July 17 of the British Society of Animal Production, it was obvious that these considerations were well in the minds of all speakers, though the question of what will be the post-war politico-economic status of the pig industry was not directly raised.

Pre-war, pig production was largely based upon imported feeding stuffs, and often, like poultry, it was carried out on specialized, intensive lines. During the last five and a half years, breeders and feeders have had to rely on home-grown food supplies, eked out where possible by swill and house refuse. Must the industry now await, even passively, the return of large importations of maize and other feeding stuffs? Or must it continue as a dispersed, small-unit enterprise—pigs on all farms—using home-produced fodders?

The change-over from pre-war methods to war-time expedients required considerable modifications of husbandry and management, yet the pig breeder had often little enough evidence or experience to help him solve the local nutritional problems exposed by the locally available foodstuffs. The investigations in Northern Ireland described by Prof. R. G. Baskett formed one of the attempts to help in the immediate adjustments of feeding methods to means. The disadvantages of oats as pig feed were well recognized, but the trials showed that, with proper precautions as to their low starch equivalent value and high fibre content, oats could be used so as to give satisfactory live-weight gains, though with less efficient food utilization. Prof. Baskett considers that similar use of oats could be made in other parts of the United Kingdom where they are the main crop, although he holds the view that, in the long run, the pre-war levels of pig population must depend upon a return to maize imports. On the other hand, practical opinion from the west of Scotland, supported by experience in parts of England, such as East Anglia, did not share this view, but favoured a more intensive exploitation of local foodstuffs, together with greater attention to appropriate management. In any circumstances the pig enterprise on a farm, whether general or specialized, needs careful planning, not merely for supply and use of feeding stuffs but also in regard to buildings, husbandry and disease control. In all these there is still great scope for improvement, which, together with more knowledge and practical experience in the feeding of potatoes, barley and dairy by-products, holds promise for an expansion and increasing efficiency of pig production. Confidence in the future would be greater provided that there were an intensification of research effort upon local problems, as well as on general principles, which could throw light upon how to make improvements within the present, or likely, cost structure of the industry.

Feeding and management, however, form only part of the problem. As Dr. John Hammond pointed out, the present low numbers of commercial pigs provide an opportune setting for the development of suitable breeding materials and methods, and of definite policies of genetic improvement. The new boar licensing scheme is a move towards restricting the kind of sire which can be used for breeding purposes, but several speakers argued that more positive methods are needed to steer the industry towards higher levels of efficient production. The nature of these positive methods can only be decided from a greater application of investigation and use of appropriate data. At present the data on fertility, weight gain and carcase characters are too sparse to serve as more than indications of what might be done. The records collected are either not used sufficiently by the breeders themselves, or are considered so expensive a luxury that breeders, with their eyes on costs, cannot afford to take them. Score card systems of judging carcase qualities can be applied; but so far are used only on a very limited scale. Yet other countries provide striking examples of the ways in which productivity measures have been successfully used in formulating and giving impetus to development.

The requirements and aims of the commercial breeder and the pedigree breeder should be more closely integrated towards an organization of the industry; whether this organization should be imposed from without, or grow up within the industry, is as yet an open question. However achieved, it should allow for a greater specialization of function within breeds and for commercial production based upon deliberate cross-breeding; for example, those interested in the coloured breeds might specialize in mothering ability, adapted for outdoor methods of husbandry; while those concerned with the Large White breed should pay particular attention to growth-rate and carcase quality.

Even so, the present pedigree system requires close examination. The average size and duration of a pedigree herd are insufficient to allow scope or time for any definite breeding policy. Dr. H. P. Donald showed that an average herd lasts only for three years, while the average number of daughters of a sire in use is two; and a family system of breeding, such as could be genetically useful, exists only in names. Moreover, the industry now relies on relatively few people for the supply of good breeding stock; according to Dr. Hammond, nine tenths of the so-called pedigree breeders are just multipliers of pedigree stock. Whether such a system is adequate or even suitable as a vehicle for real improvement is doubtful. In any event, the question of responsibility remains.

The discussion around this aspect was somewhat diffuse; but the conclusion emerged that just as it is ultimately a State responsibility to encourage the ndustry towards progress on a defined cost structure nd production aim, so also is it a State responsibility to stimulate the accumulation of the necessary nformation on performance, and on genetic principles upon which sound breeding and selection olicies can be based.

J. E. NICHOLS.

RESEARCH IN THE U.S.S.R. ON CONDITIONED REFLEXES

RECENT work on conditioned reflexes from Pavlov's laboratory is published in *Trudy hysiologitcheskikh Laboratorii Pavlov*, 11 (Moscow, 944). The director of the laboratory is now Prof. . S. Kupalov, and, in general, work has proceeded long the lines initiated by Pavlov.

Considerable attention is being paid to the different types of 'neural personality' to be found among dogs. Not only is this a major factor in the production of xperimental neuroses, but also, as is now realized, t enters into the interpretation of all the ordinary physiological results. The primary distinction is between the 'strong' type of nervous system in which onditioned reflexes are readily and strongly developed, and the 'weak' type in which the reflexes are developed with more difficulty and easily extinguished. Either type may be unstable or 'unbalanced'. V. K. Fedorov finds that neuroses develop more readily in the weak type or in the strong unbalanced ype with deficient inhibitions. 'Strength' of the nervous system is reduced by castration and old age. Neurosis affects the whole nervous system, following a definite pattern which is determined by he order of stability of the established neural processes, and is independent of the mode of causation.

L. V. Vassilieva and I. S. Rosental have made an extensive study of tactile discriminations. They have been particularly interested in the discriminaion between symmetrically opposite points of the body, which is the most difficult tactile discriminaion to establish and varies greatly in the different neural types. They have also succeeded in developing a reflex in which the dog holds out its right paw and left paw alternately; this is probably the most omplicated conditioned reflex yet established. The main object of their work was to study the reciprocal relationships between symmetrically opposite areas of the cortex.

V. I. Pavlova finds that when the conditioned stimulus is prolonged into the period of the unconditioned timulus, the reflex is strengthened in the 'strong' ype of dog but weakened in the 'weak' type. V. K. Fedorov, by repeating a conditioned stimulus at successively shorter intervals and measuring the size of the response, found that after any one stimulation the cortical cells took 3–10 min. to recover their full excitability.

V. V. Yakovleva has continued the study of what Pavlov called the 'mobility' of nervous processes, which has to do with the speed and facility of development of excitation and inhibition. It has been shown that the chronaxie of all the voluntary muscles undergoes certain quantitative changes during the development of a conditioned reflex, and E. A. Yakovleva finds that previous removal of various parts of the cortex upsets or abolishes these changes; she concludes that the cortex as a whole, rather than any one particular part of it, is responsible for these hanges in peripheral chronaxie.

CHEMICALLY STABILIZED PAPER CAPACITORS

ACCORDING to an article by D. A. McLean (*Bell Lab. Rec.*, **23**, No. 3; March, 1945), the addition of a small amount of anthraquinone to the impregnant with which the paper is treated has greatly extended the life of paper-insulated capacitors. Among impregnants, chlorinated diphenyl and chlorinated naphthalene have been used extensively. They resist oxidation and thermal decomposition, have high dielectric constant compared with mineral oil, and good electrical properties. At room temperatures, capacitors with paper dielectrics impregnated with these chemicals have a satisfactory life. At high D.C. potentials, however, and at temperatures from 50° to 100° C., rapid deterioration of the dielectric results. There is a number of compounds which substantially increase the life of capacitors on accelerated D.C. tests, when added in small amounts to the chlorinated impregnant. These stabilizers also maintain the leakage current during tests at low and relatively stable values in contrast with the rapidly increasing leakage current in unstabilized capacitors. Among the stabilizers used, the quinones were the most satisfactory, and of them, anthraquinone was chosen for commercial use owing to its high effectiveness, ready availability in pure form, low volatility and lack of toxicity.

Evidence of the diminution of electrode corrosion by anthraquinone was obtained by using capacitors in which the electrodes consisted of thin aluminium films evaporated on kraft paper before the unit was wound. In these capacitors, a small amount of corrosion of the electrodes entirely consumed the aluminium. Capacitors made with this paper were dried and impregnated in the usual manner and subjected to voltage while held at 100° C. The impregnating compound was then extracted and portions of the paper were photographed by transmitted light to show holes produced by the corrosion. The positive electrode was attacked rapidly in the unstabilized capacitors, and eventually even the negative electrode showed deterioration. After testing for 240 hours at 300 volts, the anode was very largely destroyed. The stabilized samples, however, tested under the same conditions, showed no detectable attack of either electrode in 1,000 hours, or in 495 hours at 500 volts.

Suppression of deterioration of the dielectric and corrosion of the electrodes through chemical stabilization with anthraquinone is reflected in longer life and more stable leakage current. When a linen-paper capacitor impregnated with chlorinated naphthalene is subjected to continuous D.C. voltage at 100° C., the leakage current rises rapidly. Within a very few hours a failure develops which completely short-circuits the electrodes at some point. With 0·1 per cent anthraquinone in the impregnant, the current rises less rapidly, and the life is increased by about tenfold. Increasing the amount of stabilizer to the range of one-half to four per cent produces a relatively stable leakage current. The life is then about a hundredfold as great as when no stabilizer is employed. On the basis of these and other results, a minimum of 0·5 per cent is recommended for commercial use. Kraft paper exerts a stabilizing action of its own, and consequently kraft paper capacitors, when fortified with anthraquinone, are superior in performance to stabilized linen-paper capacitors.

FORTHCOMING EVENTS

Monday, October 15

United Nations Fellowship (at 29 Gordon Square, London, W.C.1), at 6.15 p.m.—Prof. N. Bentwich: "The Educational and Cultural Organization of the United Nations".

Association of Austrian Engineers, Chemists and Scientific Workers in Great Britain (at the new Austrian Centre Swiss Cottage, 69 Greencroft Gardens, London, N.W.6), at 7.30 p.m.—Dr. F. Eirich: "Modern Views of Colloid Science (with special reference to the Ultra-Centrifuge)".

Tuesday, October 16

British Society for International Bibliography (at the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2), at 2.30 p.m.—Dr. S. C. Bradford: "Fifty Years of International Documentation" (Presidential Address); Discussion on "The Technique of making Abstracts of Scientific and Technical Papers" (to be opened by Eng.-Comdr. D. Hassie Smith, R.N.).

Eugenics Society (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Dr. W. Mayer-Gross: "Mental Health Problems in a Rural Area".

Sheffield Metallurgical Association (at 198 West Street, Sheffield 1), at 7 p.m.—Mr. J. E. Russell: "The Behaviour of Metals under Stress".

Wednesday, October 17

Society of Chemical Industry, Food Group (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Mr. D. W. Steuart: "The Nitrogen Content of Apple Juices and its Importance in Cider Making"; Mr. E. Ball: "The Raw Materials for Cider Making".

Institution of Electrical Engineers, Transmission Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. E. T. Norris: Inaugural Address as Chairman.

Institute of Fuel (at the Royal Geographical Society, Kensington Gore, London, S.W.7), at 6 p.m.—Prof. C. H. Lander: Melchett Lecture.

Institute of Welding, West Scotland Branch (at the Institution of Engineers and Shipbuilders in Scotland, 39 Elmbank Crescent, Glasgow), at 6.30 p.m.—Mr. J. S. Blair: "Some Technical Problems in the Execution of 'Pluto'".

Thursday, October 18

Institution of Electrical Engineers (joint meeting with the Royal Meteorological Society) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "Weather and Electric Power Systems" (to be opened by Mr. J. S. Forrest, Mr. H. W. Grimmitt, Mr. A. J. Drummond and Wing-Comdr. R. M. Poulter).

Royal Society of Tropical Medicine and Hygiene (at Manson House, 26 Portland Place, London, W.1), at 8 p.m.—Dr. C. M. Wenyon, F.R.S.: "Tropical Medicine in War and Peace".

Friday, October 19

Physical Society (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. Bengt Edlén: "The Spectral Structure of the Inert Gases". (Fellows of the Royal Astronomical Society are invited.)

Institution of Mechanical Engineers (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Prof. Andrew Robertson, F.R.S. (Presidential Address).

Institute of Physics, Scottish Branch (joint meeting with the Industrial Radiology Group) (at the Institution of Engineers and Shipbuilders in Scotland, 39 Elmbank Crescent, Glasgow), at 6.30 p.m.—Mr. E. Thomas: "The Radiography of Welds in High Pressure Steam Pipes".

Saturday, October 20

Royal Institute of Chemistry, London and South-Eastern Counties Branch (at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1), at 2.30 p.m.—Discussion on "The Publicity of Science, with particular reference to Chemistry" (Dr. O. J. R. Howarth, O.B.E., Mr. C. F. Brown, Mr. G. A. Jones, and others).

Institution of Mechanical Engineers, Graduates' Section (at Storey's Gate, St. James's Park, London, S.W.1), at 3.30 p.m.—Mr. R. Gore: "A System of Production Control".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer in Chemistry at the Widnes Municipal Technical College—The Clerk to the Governors (Oct. 15).

Technical Laboratory Assistant in the Chemistry Department, University College of South Wales and Monmouthshire, Cathays Park, Cardiff—The Registrar (Oct. 16).

Senior Lecturer in Civil Engineering—The Principal and Clerk to the Governing Body, Wigan and District Mining and Technical College, Wigan (Oct. 18).

Junior Assistant Physicist (temporary) in the London County Council's Hospitals Service—The Medical Officer of Health (S.D.6), London County Council, County Hall, London, S.E.1 (Oct. 19).

Lecturers in Mechanical Engineering, Production Engineering, and Physics in the Chance Technical College—The Chief Education Officer, 215 High Street, Smethwick (Oct. 20).

Lecturer in Mechanical Engineering at the Brighton Technical College—The Education Officer, 54 Old Steine, Brighton (Oct. 20).

Assistant Lecturer in the Mathematics Department—Th Clerk and Treasurer, Technical College, Bell Street, Dund (Oct. 22).

Two Highway Engineers (Ref. No E.1988.A), and Railwa Engineer (Ref. No. 1989.A), for service in China with the Unite Nations Relief and Rehabilitation Administration—The Ministry Labour and National Service, Technical and Scientific Register, Roo 670, York House, Kingsway, London, W.C.2 (Oct. 22).

Laboratory Technician (Public Health Department) with knowledge of Public Health Bacteriology (including milk examin tions) and/or Clinical Pathology, and a Technical Assistant (Boroug Engineer's Department) for work on repairs to war-damaged houses The Town Clerk, Finsbury Town Hall, Rosebery Avenue, Londo E.C.1 (Oct. 23).

Graduate in Chemistry in the Senior Science Department of th Southport Technical College—The Chief Education Officer, 1 Eas bank Street, Southport (Oct. 25).

Principal of the County Technical College, Guildford—Th Chief Education Officer, County Hall, Kingston-upon-Tham (Oct. 26).

Records Officer to the Nuffield Health and Sickness Recor Bureau, for the supervision of collection and analysis of informatio concerning morbidity in the West of Scotland—Mr. R. Morriso Smith, 135 Buchanan Street, Glasgow, C.1 (Oct. 27).

Lecturer in Chemistry, with qualifications in Inorganic Chemist and Metallurgy—The Principal, Heriot-Watt College, Edinburg (Oct. 29).

Assistant Chief of Research by firm in N.W. England engage in a highly technical form of manufacture on a large scale—Th Ministry of Labour and National Service, Appointments Departmen Technical and Scientific Register, York House, Kingsway, Londo W.C.2, quoting F.4367.XA (Oct. 29).

Inorganic Chemist (qualified) to supervise chemical control Middlesex factory manufacturing cast plaster panels—The Minist of Labour and National Service, Appointments Department, Technic and Scientific Register, Room 670, York House, Kingsway, Londo W.C.2, quoting F.4964.XA (Oct. 31).

Assistant to Head of Technical Engineering Departme of large Iron and Steel Works—The Ministry of Labour and Nation Service, Appointments Department, Technical and Scientific Registe Room 670, York House, Kingsway, London, W.C.2, quoting C.2683XA (Oct. 31).

Technical Assistant in the Department of Chemistry—The Registrar, The University, Bristol 8 (Oct. 31).

Biologist and a Physicist at the North-Eastern Forensic Scien Laboratory at Wakefield—The Establishment Officer, (Room 321 Home Office, Whitehall, London, S.W.1 (Nov. 6).

Engineers for development, indoctrination, and contact work lubricants field: (a) A.M.I.Mech.E., and preferably with University de gree, also experience with automobile firm (Reference No. C.2785.XA (b) A.M.I.Mech.E., and preferably with University degree, also ex perience in oil engine design and operation (Reference No. C.2786.XA (c) A.M.I.Mech.E., and preferably with University degree, also ex perience with steam power plant and general industrial engineerin (Reference No. C.2784.XA), (d) A.M.I.Mar.E., and preferably wit University degree, also experience with marine diesel manufactur (Reference No. C.2783.XA)—The Ministry of Labour and Nation Service, Appointments Department, Technical and Scientific Registe Room 670, York House, Kingsway, London, W.C.2, quoting appr priate Reference No. (Nov. 12).

Research Officer, Dairy Research Section, Council for Scien tific and Industrial Research, Melbourne—The Secretary, Australia Scientific Research Liaison Office, Australia House, Strand, Londo W.C.2 (Nov. 12).

Senior Lecturer in General Science and Scientific Metho in the University of Melbourne—The Secretary, Universities Burea of the British Empire, c/o University College, Gower Street, Londo W.C.1 (Nov. 15).

Professor of Physics—The Registrar, University College, Singleto Park, Swansea (Nov. 17).

Hackett Professor of Agriculture in the University of Weste Australia—The Agent-General for Western Australia, Savoy Hous 115 Strand, London, W.C.2 (Nov. 30).

County Surveyor to the Devon County Council—The Clerk t the Council, The Castle, Exeter, endorsed "Appointment of Count Surveyor" (Dec. 31).

Lecturer in the Department of Physiology—The Secretary, The University, Aberdeen (Jan. 15).

Professor of Geology, and a Professor of Industrial Chem istry, in the Farouk I University, Alexandria—The British Coun (Appointments Department), 3 Hanover Street, London, W.1.

Two Assistants in Agricultural Entomology in the Adviso Entomological Department, School of Agriculture, Cambridge—F. Petherbridge.

Officers (2) for the Intelligence Section of the Minera Resources Department, Imperial Institute—The Establishme Officer, Imperial Institute, South Kensington, London, S.W.7.

Trained Technician in the Physiology Department, an Demonstrators (temporary) in Physics, Biology and Chemistry—The Vice-Dean, St. Bartholomew's Hospital, at Queen's Colleg Cambridge.

Lecturer in Bacteriology in the University of Queensland—The Agent-General for Queensland, 409 Strand, London, W.C and the Secretary, Universities Bureau of the British Empire, c/ University College, Gower Street, London, W.C.1.

Teacher of Physics and Chemistry to first M.B. and Intermedia Science standard—The Principal, Technical Institute, Folkestone.

Lecturers in the School of Engineering for Mechanic Engineering and Electrical Engineering—The Principal, Leicest College of Technology and Commerce, Leicester.

Qualified Production Engineer, and a Teacher (man or woma of Biology—The Clerk to the Governors, Wolverhampton a Staffordshire Technical College, Wolverhampton.

SCIENCE AND NATIONAL DEFENCE

THE debates in both Houses of Parliament on the Charter of the United Nations on August 22 and 23 showed how widely it is realized that the secret of the atomic bomb cannot be kept indefinitely by any one nation, and that the only alternative to pooling knowledge is a further competition in armaments research of a new type which must inevitably plunge the world into disaster. The Lord Chancellor very rightly said that to try to keep the secret would encourage research in the methods of destruction in every country of the world. The debate further demonstrated that the Government is endeavouring to formulate a rational policy towards the new development, and that the new policy must be based on the full and free exchange of fundamental scientific knowledge. As Prof. Niels Bohr has pointed out, no control can be effective without free access to full scientific information. President Truman has, in effect, lent his support to that same condition by his executive order of August 27, calling for the earliest possible release and free dissemination of scientific and industrial information gained from Germany and Japan. This order covers all information concerning scientific, industrial and technical processes and inventions, in enemy countries or in liberated areas, if such information is of enemy origin or has been acquired or appropriated by the enemy. This means that the details of Germany's experiments with atomic bombs will be shared and made public when the chiefs of staff decide that it is safe to do so.

While the full meaning of the order is perhaps open to question, it points to a situation which calls for an early meeting of the Powers to discuss the whole problem of atomic energy and its control. The pressure in the House of Commons debate for some form of international control in relation to research and to production and through a system of inspection, scarcely took account of the fact that no appropriate international authority yet exists, and that even the Security Council at present scarcely meets the requirements. Preliminary discussions between the United States, Great Britain, the U.S.S.R. and at any rate China could do much to prepare the way; the respite of two or three years will be none too much to elaborate the essential structure of the control and inspectorate required and to secure the approval and support of all the nations concerned.

Meanwhile, it is essential that there should proceed as a matter of urgency the full re-evaluation of the whole structure of the defence of Britain in the light of these considerations, and particularly of the means for watching and controlling new developments in the technique of scientific warfare. From this point of view the statement relating to the atomic bomb issued by the Department of Scientific and Industrial Research demands close study, and Lord Hankey's recent book is also opportune*. In the Lees Knowles Lectures which form the basis of his book, Lord Hankey gives a brief synopsis of the development of government machinery in Britain for the formulation and co-ordination of defence policy, from the establishment of the Committee of Imperial Defence at the beginning of the present century up to the delivery of the last lecture of the series on March 9, 1945. The basic principles he establishes and the lessons he draws for the future cannot be disregarded by any who seek to appraise the new situation. Although the fact could not be disclosed in his lectures, Lord Hankey had himself been in touch with many aspects of the development of the atomic bomb, and in a letter in *The Times* of August 11 he supplemented the official accounts in respect of the part played by the Scientific Advisory Committee of the War Cabinet in 1941.

---

* Government Control in War. By the Rt. Hon. Lord Hankey. (Lees Knowles Lectures, 1945.) Pp. 90. (Cambridge: At the University Press, 1945.) 4*s*. 6*d*. net.

Lord Hankey's story will be to many people unexpectedly reassuring. Within the narrow interpretation of a defensive policy, both in 1914 and in 1939 our preparations were sounder, more thorough and complete than has been generally realized or believed, for all that, like the other peace-loving nations, the outbreak of war found Britain with armaments totally insufficient in numbers and efficiency to withstand the enemy. That unpreparedness resulted from a failure, not of our system of imperial defence, but of the political working of the constitutional system of Government by Parliament and people. This is the fundamental lesson, and Lord Hankey insists that the only real check on a recurrence of our past unpreparedness is the spread of greater knowledge and understanding among the people as to the importance of national defence.

The challenge of the atomic bomb at least presents us with an unrivalled opportunity for that task of educating public opinion as to what is involved, and raising the question of national defence above party politics. Lord Hankey in his concluding lecture appealed specially to the universities to play their part in the task of promoting a better understanding of the lessons of history in their application to imperial defence; and the part which men of science have played in the development of the atomic bomb adds weight to Lord Hankey's emphasis on the responsibility even of undergraduates in this matter. Speeches in the House of Commons and correspondence in the daily Press provide abundant evidence of the work yet to be done to build up a sound and healthy public opinion, and combat the shallow, if not thoroughly unsound, thinking on national service and like issues that has already found expression.

The first governing principle laid down by Lord Hankey, that final control must remain in the hands of statesmen, working in the closest co-operation with the Service chiefs, with the Prime Minister of the day alone as head, was in fact firmly asserted by Mr. Bevin when he stated that he is not prepared to see control of the atomic bomb handed over to the military authorities at all. Control is the responsibility of the Government, and military authorities must remain the Government's advisers. Again, Lord Hankey points out that, while in the grand strategy of the War the views of the Service chiefs must usually prevail, even here the last word must rest with the statesmen, who are responsible for policy and for distributing the resources of the country in the manner best calculated to win the war. Relations between statesmen and commanders-in-chief should be conducted on the principle of selecting the best men available, giving them a free hand, and backing them up to the hilt with a minimum of interference. Governments are entitled to ask their commanders-in-chief to consider alternative plans to their own, but should rarely ask them to carry out plans in which they do not believe. In time of peace, the Prime Minister, whether with or without a deputy, but in association with some of his colleagues, should always be responsible for, and well acquainted with, our preparations for war.

It is because, as Lord Hankey shows, these principle were observed very closely in practice by Mr. Asquith and Mr. Lloyd George in the First World War, and by Mr. Chamberlain and Mr. Churchill in the Second World War, and that for forty years our Prime Ministers, as presidents of the Committee of Imperia Defence, have been responsible for preparations fo war, that it can be claimed that we in Britain hav evolved a system which is superior to that of ou enemies or of any nation in the previous history o war. Lord Hankey not only pays a handsome tribut to Mr. Lloyd George as the founder of our moder system of control; he also maintains that ou administrative preparations in 1939 were as complet as they could be, within the limits of our policy an the finances made available; and while he prefer on the administrative side the more flexible syste adopted in 1916–17, he insists that our chiefs-of-sta organization to-day is the best example the worl has ever known of a great joint general staff t cover and combine all aspects of inter-Service operations. We already possess a Combined General Staff and in a form which permits rapid transformatio from a war system to a peace system and vice versa

As to methods, Lord Hankey concludes that th most successful form of administrative control is tha initiated by Mr. Lloyd George: a small War Cabine composed of a few Ministers of great experience, som at least of whom are free from departmental or heav Parliamentary duties and able to give their whol time to the central problems of the war and to lif some of the weight off the Prime Minister. Furthermore, Lord Hankey suggests that as a matter of overriding principle, the Prime Minister must have th system and organization that his methods and temperament and the circumstances of the times requir Machines are made for men and not men for machine and in urging generally the need of flexibility so tha the system is adaptable to different temperamen and circumstances, Lord Hankey attributes th success of our present system largely to its flexibilit

That flexibility is attested by the development the Directorate of Tube Alloys described in the rece paper of the Department of Scientific and Industri Research. Indeed that statement in itself might we be taken as a striking testimony to the adaptabilit of our existing system. Lord Hankey's long experience largely endorses some of the observatio in the final report of the Select Committee on Nation Expenditure for the Session 1944–45; but althou it is not in accordance with the principles that he enunciates to place on scientific men as such the executive responsibilities which Dr. Haden Guest suggested, Lord Hankey, like the Select Committee, considers that further measures are required to secure in future a much greater use of science in all its branches. It is understood that the Office of Scientific Advisers to the Ministry of Production has already been allowed to lapse, and this step should not be allowed to pass unchallenged. A most important part of the central system in Britain, Lord Hankey considers, should be a strong scientific and engineering section to watch all developments in physics, chemistry, explosives, civil, mechanical, electrical and chemical engineering, metallurgy, biology, nutrition, medicine, etc., from the point of view of their possible use by an enemy and by ourselves; to plan the measures to be taken to neutralize new developments, and to lay out research. Scientific work on defence accordingly should now be brought to the centre and coordinated by a special organization attached to the Committee of Imperial Defence. This might include a small directing committee, on the lines of the existing Scientific and Engineering Advisory Committees, with a large panel of consultants and a secretariat of whole-time specialists. Each Government department concerned in imperial defence would have its own scientific division as at present, closely linked with the central body; and, like the Select Committee, Lord Hankey refers to the need for organizing scientific workers in advance for war emergency, and for including in our war arrangements plans for expansion and for training the large numbers required.

Whether the Select Committee was aware of the atomic bomb preparations or not when preparing its report, such developments were clearly in Lord Hankey's mind in delivering these lectures, and scientific workers would have welcomed a much fuller discussion of the scientific aspects of defence policy and organization than the page or so they receive in this book. Moreover, while Lord Hankey's letter to *The Times* was concerned to pay tribute to the part played by the Scientific Advisory Committee and to the collective influence of Sir Henry Dale, Prof. A. V. Hill, Sir Alfred Egerton, Sir Edward Appleton and Sir Edward Mellanby prior to the establishment of the Directorate of Tube Alloys of the Department of Scientific and Industrial Research, neither there nor in his book does he touch on the larger question of the combined chiefs of staff organization or the practicability of international control. These, however, are the major points of concern at the moment. The atomic bomb itself is the outcome of a remarkable demonstration of co-operative research and enterprise between the scientific workers of Great Britain, the United States and Canada, with others of the United Nations. What is in dispute is the practicability or otherwise of devising a system of co-operative international control.

As has already been noted, no international authority yet exists to which the exercise of control could be entrusted: the Security Council, as at present constituted, would in practice merely mean entrusting the responsibility to Great Britain, the United States, the U.S.S.R. and a few other Powers, and the proposal might or might not be acceptable to other members of the United Nations. Meanwhile, however, it is essential that the full implications of the situation should be brought out; and either international control dismissed as impracticable for reasons clearly given, or a scheme worked out which will satisfy the essential conditions, even if the ultimate repository of the control yet remains to be determined.

Brigadier J. L. P. Macnair, referring to the leading article in *Nature* of July 14, has suggested that the Security Council should have at its disposal an armaments development department, staffed by scientific men and service officers of all nations and equipped with all the resources necessary to keep abreast of the results flowing from basic research. It should be in the power of the Security Council, on the advice of this department, to call on any nation for details of technical advances in war-like stores, and refusal to comply with such a request should be regarded as evidence of intended aggression. If the Council succeeds in establishing a reputation for impartiality, such details would probably be readily made available in the cause of peace, certainly up to a time sufficiently close to that of a threatened aggression for the armaments development department to keep abreast of the work, using its own resources.

It may, of course, be maintained that secrecy in the development of full-scale experimental equipment for the manufacture of any new weapon of war is still possible, and this objection applies equally to any proposals for the control and international inspection of the armaments industry as a whole. On the pessimistic view, international control of research into atomic energy would mean nothing; any powerful nation with a large hinterland could break the convention, leaving out of account the possibility of further developments.

Sir Arthur Salter, who in the debate urged that the military provisions of the Charter have become obsolete in the light of this new weapon unless we succeed in controlling it effectively, stressed the factor of speed, and did not minimize the difficulties in achieving adequate control. Like Prof. Niels Bohr, he recognizes that control measures may demand the abolition of barriers hitherto considered necessary to safeguard national interests, but now standing in the way of common security against unprecedented dangers. Sir Arthur thinks it may involve some restriction of research that may be distasteful to all the traditions of science. Research on atomic energy, he believes, will have to be conducted under conditions of public scrutiny which will take adequate steps at every stage to control its application. Regarding the Atomic Energy Advisory Committee as a first step in this direction, he suggested that the secret of the atomic bomb should only be shared as a counterpart to an assured international control in each country which is given possession of the secret.

Sir Arthur is thus thinking on similar lines to Sir John Anderson, who has already stated that the essential features of such a control are, first, an undertaking by each nation to submit all relevant information in its possession to a central authority having unrestricted rights of inspection, and secondly, the possession by such central authority of the means of enforcing the undertaking against any recalcitrant nation. Such an international and predominantly foreign control in each country of the most important weapon of war clearly runs counter to every national prejudice and tradition, and the handling of this precarious situation will demand the utmost goodwill of all nations. Could agreement be reached, however, the contribution it would make to the removal of obstacles to mutual confidence and the promotion of harmonious relations would be incalculable.

The House of Commons was clearly fully alive to the dangers of attempting to preserve secrecy. Mr. Price pointed out that a barrier between the Great Powers of the Security Council in military secrecy and scientific research would intensify political barriers, and might lead to division into two camps rigorously guarding their military secrets and scientific inventions, in complete contrast to the spirit of free inquiry, untrammelled by secrecy, relentlessly searching after truth, which is the mainspring of science. Nor was it forgotten that the Charter establishes no effective international authority, and that we are still faced with the task of creating an instrument of unchallengeable power which at the same time will secure liberties under the reign of law that men will make great sacrifices to maintain. Mr. Boothby pressed very strongly for the establishment of a scientific section of the Economic and Social Council; but while Mr. Bevin, in winding up the debate, added very little to what had been said, his speech indicated that the Government is viewing the whole question realistically and in the right perspective.

We have to consider control, said Mr. Bevin, not merely of the atomic bomb but also of the whole advance of science in the field of war, and it is the aim of the Government, through the world organization, to eliminate the desire to exploit the discoveries of science for the purposes of war, and turn them into channels which will serve human welfare. Consideration of disclosure of the secret of the atomic bomb should be postponed until the world organization is established and the whole question of control of dangerous weapons can be discussed, including that of the essential raw materials. So far as it is necessary to implement the work of the world organization to control scientific research or the manufacture of weapons, we should endeavour to direct our policy so that such weapons become unnecessary, and keep a careful watch to ensure that no Government starts out with war-like intentions.

The debate on the United Nations Charter clearly affords no ground for undue optimism as to the achievement; nevertheless it was recognized that science itself is not to be blamed for the prostitution of scientific effort in such developments as the atomic bomb, and speaker after speaker referred to the necessity for a moral basis for the new effort to achieve world order and international control. Man's intellectual and scientific attainments have far outdistanced his achievements in the moral sphere, and even if there is built up in an international technical inspectorate a tradition, as Dr. J. B. Conant has suggested, in which professional loyalties are anchored to the United Nations, control will still be ineffective without some advance in the whole standard of national and international morality which will accept the sacrifices of national independence involved.

That must be largely a matter of creating an informed public opinion, such as Lord Hankey stipulates and to which Mr. Bevin also referred in the close of his speech. The Government is clearly moving along the right lines, and the statements relating to the atomic bomb should do something to assist in this fundamental task of educating public opinion in this vital matter. More might well be done by the appointment of a committee to consider appropriate means of parliamentary control of public expenditure on research, as recommended by the Select Committee on National Expenditure; and it is to be hoped that these new developments will lead the new Parliament to give close attention to this whole question of research and development as recommended in the final report for last session of that Committee

The challenge to scientific workers in the debate as in Lord Hankey's book, is unmistakable. If the broad structure of the nation's organization for defence is on right lines, there are still ways in which it can be further improved, and the full contribution of science in national defence facilitated and made more effective. Besides criticisms from the Select Committee on National Expenditure, there are wise suggestions made by Prof. A. V. Hill to the Parliamentary and Scientific Committee for breaking down departmentalism and the traditional secrecy of science in the Services, and bringing the departments into closer touch with the wide horizons and most recent developments in science which are still pertinent.

But Lord Hankey's reminder of the special responsibility which lies upon the man of science in the task of forming an educated public opinion has been reinforced by a noble appeal from Prof. Niels Bohr. The scientific man, more than most men, is in a position to appreciate the constant and dire peril of civilization unless some effective international control can b devised and operated. On him must fall, too, some measure of responsibility for devising and operating that control. He knows that the march of scienc cannot be stopped, and that the foundation for any international control must be full and free interchange of fundamental scientific knowledge. He may indee never have a more favourable opportunity of pressin for the removal of all the restrictions that in the las thirty years have been imposed upon such communications. But he knows, too, the truth of General MacArthur's words at the Japanese surrender ceremony, that man needs a growth in his spiritual powers to equal the almost matchless advance in science; scientific workers are prepared to assist in any way possible to solve the present crisis of humanity in a manner worthy of the ideals for whic science through the ages has stood. The first practical step to that end must be the establishment of full freedom of communication and dissemination of knowledge.

WILHELM DILTHEY

Wilhelm Dilthey

An Introduction. By Prof. H. A. Hodges. (International Library of Sociology and Social Reconstruction.) Pp. x+174. (London: Kegan Paul and Co., Ltd., 1944.) 10*s.* 6*d.* net.

As Prof. H. A. Hodges says in the beginning of his introduction, this is the first book on Wilhelm Dilthey to be published in England, and it is overdue. Why Dilthey did not attract attention in England earlier is puzzling. The reason is possibly that the most interesting parts of his work only appeared after his death in 1911. Eleven volumes of "Gesammelte Schriften" came out between 1914 and 1936. The challenging "Einleitung in die Geisteswissenschaften" ("Introduction to Human Studies", as Prof. Hodges translates it) was indeed published so long ago as 1883, but that remarkable work is more the statement of a problem or a challenge than an answer.

Still, the challenge was one which should have been taken up in Britain. For in that book, Dilthey shows that what is wrong with the *Geisteswissenschaften*—human studies—is that it has been continuously assumed that they either ought to be sciences like physics or be philosophy. Quite obviously, he maintained, they are neither one nor the other. Attempts to reduce history to a natural science in the manner of Buckle or to reduce it to philosophy are equally ridiculous. It clearly has its own methods and its own standards.

Now that was very much a challenge to us. We had gone so far in Britain in the direction Dilthey deplores that we have no word corresponding to the German *Wissenschaft*—any systematic thorough discipline with approved methods and standards. Science means in English natural science. Our study of politics and morals has either been predominantly philosophical and therefore not sufficiently empirical or historical, or had its facts falsified to make them fit into an atomism impressed by the example of physics; it had to follow the example set by Hegel or by Bentham, the specific German or the specific English pattern. Karl Marx made a gallant attempt to unite these two sources; but the German and the Hegelian in him conquered the empirical.

Dilthey's attempt is more interesting and far more promising. He was a Kantian. He started with a firm belief in Kant's criticism of metaphysics. The side of Kant which attracted him was the empirical. He wanted only to consider historical studies with the same impartial scrutiny as Kant had given to physics. He held, and rightly, that the rise and progress of historical study in the nineteenth century was in its way as remarkable as the rise of physics before. He proposed in his thoroughgoing empiricism to take history as he found it; not to say it ought to be like physics or like philosophy, but to discover what it was. So he set himself to write a critique of historical reason to be set out against Kant's critique of pure reason.

Can one recognize that the understanding of human beings and society requires a certain imagination, a sympathy, a power of putting oneself in the place of others, which the understanding of the physical world does not, and yet give to this very different kind of understanding the systematic thoroughness and the objectivity of the physical sciences? That is Dilthey's problem. He never completed his critique of historical reason, but he wrote a great deal towards it. Prof. Hodges gives an admirable account of the conclusions to which he came: his far-reaching contributions to psychology and to sociology as well as to historical method.

As Prof. Hodges points out several times, there is considerable similarity between Dilthey's thought and that of the late Prof. Collingwood. There is, however, this important difference. Collingwood was a philosopher and historian. He was primarily interested in history, in which he was an authority, and not in the other human studies like psychology and economics. Dilthey recognized that mind and body, man and Nature, being so closely knit, the 'human studies' merge at one end of the scale into the natural sciences; but he always maintained that they must all be taken together. The inquiry which co-ordinates them all gives the *Weltanschauung* which is the goal of our understanding and must itself be one of the *Geisteswissenschaften* and follow their methods.

What is the final co-ordinating inquiry which will give what Dilthey calls the *Gesamtaufbau*? Is it sociology or history? Dilthey seems sometimes to have put one and sometimes the other of those two in pride of place. Prof. Hodges thinks that he should have come firmly down on the side of sociology. I should myself press the other alternative.

I hope I have said enough to show the extreme interest of the issues raised and the conclusions set forth in this long and masterly account of Dilthey's thought, supplemented as it is by selections from the most important of Dilthey's discussions. I hope the book will be widely read. A. D. LINDSAY.

A FLORA OF FAMILIAR ENGLISH PLANTS

Common Wild Flowers

By John Hutchinson. (Pelican Book A.153.) Pp. xxx+222+14 plates. (Harmondsworth and New York: Penguin Books, Ltd., 1945.) 9*d.*

This admirable little book should supply a long-felt want by all lovers of the English countryside. Handy in form and size, it can be carried comfortably on country rambles, and with its aid many of the wild plants found can be easily identified. As an experienced botanist Dr. Hutchinson brings a skilled experience in dealing with the identification of plants by those having no botanical knowledge.

The introduction deals briefly with the salient features of floral structure and then goes on to describe the use of the key. The key is divided into three sections dealing with the Gymnosperms, the Dicotyledons and the Monocotyledons respectively. These are very clear, and the layman should have no difficulty in determining the genus and species of any plant described in the book. The plants selected number 202, and these are well chosen and represent familiar plants most of which may be found on country rambles in almost any part of Great Britain. Only six Monocotyledons are listed; perhaps the number might have been extended by the inclusion of a few of the marsh plants so common in many parts of the country. Each plant has a page of detailed description and is accompanied by excellent drawings of the shoot, leaves, flower and floral structures, and in many cases the fruit and seed. These drawings are really well executed, and the reproduction is excellent. With all these aids set down by a skilled botanist, the collector should have no difficulty in running down a specimen.

But more is given than the botanical and popular name of each species, for the habitat in Great Britain and the distribution of the species abroad is described in many cases, and in dealing with trees the characteristics of the wood and the uses to which it is put are generally given. This is a most desirable feature, and gives the layman a glimpse into the interesting features of the varied distribution of plants over the surface of the earth. In addition to the illustrations attached to each species, twelve pages of photogravures are added of some well-known plants such as the foxglove, cowslip, sweet violet. These are well reproduced; but it is a question whether this space might not have been devoted to the description of twelve more species.

Many features of biological interest are frequently introduced, as in the case of the behaviour of alder seeds after shedding. Such features make the book so much more than a mere list of plants.

This book, so well designed for its purpose, can do a great deal to promote an interest in plant life, and in many instances will lead on to the desire for a more extended knowledge of the green mantle covering the earth, whether it be in the direction of geographical distribution or the grouping of different kinds of vegetation in different parts of the country. For the reader who, after practice with this book, desires to extend his knowledge to other plants of Britain a short list of books is given.

Besides appealing to the layman interested in natural objects it should be of value in the schools. Some knowledge of classification and of plants in their natural habitat is of fundamental importance, and unfortunately it is an aspect of botany which in many British universities is treated in an inadequate fashion.

There is need for similar books on geology constructed on a regional basis, so that a general knowledge of earth structure and its varied plant cover may become a common possession of all educated people.

F. J. LEWIS.

STEAM TABLES AND STEAM POWER

The 1939 Callendar Steam Tables

Compiled and edited by G. S. Callendar and A. C. Egerton. (Published for the British Electrical and Allied Industries Research Association.) Second edition, with New Appendix on Properties of Compressed Liquid Water. Pp. 70. (London: Edward Arnold and Co., 1944.) 12*s.* 6*d.* net.

THE successful design of improved steam power-cycles utilizing high pressures and temperatures depends entirely on an accurate knowledge of the properties of steam. An increase in the efficiency of the steam cycle by 1 per cent represents a large annual saving in the coal cost for a modern power station; but this degree of accuracy in the calculations can only be attained if the tabulated properties of steam at extended pressures and temperatures are reliable. Practical evidence was obtained of the inaccuracy at high pressures of the earlier steam tables when high-pressure boilers were first constructed, for the calculated heat transferred to steam plus the measured losses in the boiler was greater than the heat supplied by the fuel. Since the losses in a modern boiler are small, and can be measured with a high degree of accuracy, it was clear that the tabulated total heats of steam were greater than the true values.

The work of the late Prof. H. L. Callendar is outstanding in the measurement of the properties of steam, and this research has been continued by Mr. G. S. Callendar and Sir Alfred Egerton, with the support of the British Electrical and Allied Industries Research Association. Research has also been conducted in the United States and on the Continent, with close co-operation between the investigators and the holding of three international conferences.

The following table has been compiled in order to compare the values of the total heat of saturated steam at various pressures as quoted by several investigators.

TOTAL HEAT OF DRY SATURATED STEAM ABOVE WATER AT 32° F. IN B.TH.U. PER LB.

Investigator and date	Pressure in lb. per sq. in. absolute 1	15	200	500	1000	2000	3000

* 1915 Tables limited to 500 lb. per sq. in. pressure.
† Based on additional data by Mollier and revised equations.

The general deductions which may be drawn from these above figures are as follows: (*a*) There is a slight increase in the total heat values for steam at low pressures below atmospheric. (*b*) Little change has occurred in the total heat values of steam at atmospheric pressure. (*c*) There is a decrease in the total heat values for high-pressure steam amounting to about 3 per cent at 1,000 lb. per sq. inch and to 8 per cent at 2,000 lb. per sq. inch. (*d*) Since 1932 the values over the whole range of pressure are sufficiently in agreement for practical design purposes, and within the limits of tolerances set by the Third International Steam Table Conference, 1934.

In connexion with this comparison, it should be noted that the Callendar 1939 values are based on actual measurements of total heat, whereas other tables are based on values deduced from specific heat and volume measurements. The fact that the two systems of determination are now in substantial agreement indicates that the recently published properties of steam cannot err greatly from the true values.

The numerical values in the second edition of the Callendar 1939 Tables are unaltered from those in the first edition of these tables; but a new appendix on the properties of compressed liquid water at high pressures and temperatures has been added. These tables are the result of much careful research and planning, and should meet the requirements for many years of engineers concerned with the design and testing of steam power plant or of heating and ventilating systems.

H. HEYWOOD.

LOGNORMAL DISTRIBUTIONS

By PROF. J. H. GADDUM, F.R.S.
University of Edinburgh

A LARGE part of statistical theory is based on the assumption that measurements are distributed in normal probability curves and that the variance is constant. The normal curve was discovered by de Moivre in 1753 and developed as a useful mathematical tool by Laplace, Gauss, Maxwell and others. It has a number of interesting properties, and various attempts were once made to establish a law of Nature known as the 'normal law of errors', which implied that measurements ought always to be distributed in this way. These attempts were undeservedly successful. The use of the adjective 'normal' in connexion with this law implies more than is justified by the facts, whereas in fact the adjective is established by custom and provides a convenient label for distributions of this type.

Referring to the normal law in the introduction to his "Thermodynamique", H. Poincaré (1892)[1] quotes the remark that "Everybody firmly believes in it because the mathematicians imagine it is a fact of observation, and observers that it is a theory of mathematics". Since that time the mathematical conditions for normality have been firmly established[2], but the best evidence that these conditions are fulfilled in any particular case is still the observation that the distribution actually is normal. It is therefore important, either to show that observations are normally distributed, or to convert them into a form which is normally distributed, or at least has the best possible chance of being normally distributed.

In some cases the normal curve gives a very close approximation to the observed facts. These cases are the exception rather than the rule; but it is usually possible to transform the distribution by means of some function of the actual observations which is normally distributed, so that if this function is used instead of the observations themselves the subsequent calculations are simplified and their scope is extended. This device is well known to statisticians, but not used so widely as it should be. It is obviously justified in simple cases. Suppose, for example, that the original observations were measurements of the diameters of drops in an emulsion (d) and that it was found that the distribution of d was not normal, but that the distribution of d^3 was normal. This would mean that the volume of the drops was normally distributed, and would show that it would be more convenient to consider the distribution of volumes than the distribution of diameters. The size of the drops can, in fact, be measured in a number of different ways. There is no particular reason why the original observations should represent the most convenient way, and no particular reason why the most convenient way should not be used even if it is less obviously reasonable than in the example given above.

"The linear scale, since it was first cut on the wall of an Egyptian temple, has come to be accepted by man almost as if it were the one unique scale with which Nature builds and works. Whereas it is nothing of the sort" (Bagnold[3]).

Even if one method of measurement gives normal distributions, it necessarily follows that most others will not; and since it is unlikely that the appropriate method will often be chosen first, it is only to be expected that most distributions will not be normal unless care is taken to select the appropriate method of measurement[4].

The second condition for the unfettered use of statistics is that the variance of the distribution shall be constant, or at least shall vary in some predictable way. If these two conditions are fulfilled, it is easy to calculate the significance of differences, regression lines, correlation coefficients, the analysis of variance and so on; but, if not, the possibilities are very restricted. For example, if the distribution is not normal, it is unjustifiable even to assume that the arithmetic mean is the best estimate of a quantity that can be derived from a set of measurements of it. Recent developments in statistical technique have thus greatly increased the importance of methods for normalizing distributions by altering the method of measurement, or by transformation of each observation by some suitable device such as taking its logarithm. This is particularly important when the standard deviation is large compared with the mean. When it is small, all ordinary transformations of this kind have less effect, and in the limit when it is very small no such transformation has any effect at all.

The theoretical justification for using normal curves depends on the mathematical fact, which is true within certain defined limits[2], that the sum, or arithmetic mean, of a large number of variables tends to be normally distributed even when the individual variables are not. If an observation (x) depends on the sum of the effects of a large number of small causes acting at random, and if each effect is independent of x, the distribution is likely to be normal. If it is not normal, we assume that this is because x is not measured in the right way. We find that $f(x)$ is normally distributed and we therefore transform our observations of x by converting them into observations of $f(x)$. The normal shape of the distribution of $f(x)$ is presumably due to the random combination of numerous causes each of which has a small effect on $f(x)$, and this effect is independent of $f(x)$. The effect of each of these causes on x will be proportional to $dx/d\,f(x)$, and Kapteyn[5] calls this quantity the 'reaction'. For example, if $f(x) = \log x$, the reaction is x. The effect of each small cause on $\log x$ is independent of $\log x$ (and of x); its effect on x is therefore proportional to x. If x is an astronomical observation involving a reading on a dial, the absolute value of x is usually irrelevant; the reaction is likely to be constant and the distribution is likely to be normal. In most scientific observations, however, the absolute value of x is not irrelevant. A fine day which adds a given weight to a large animal is not likely to add the same weight to a smaller animal. The gains in weight are more likely to be proportional to the size of the animal. In other words, the effect of the fine day on the logarithm of the weight is more likely to be constant than its effect on the weight, so that the logarithm of the weight is likely to be normally distributed. The assumption that this will be so is not likely to be exactly true; but it is likely to give a closer approximation to the facts than the assumption that the effect is independent of the weight.

The problem has been tackled in a rather different way by Curtiss[6], who discusses methods of calculating the appropriate transformation from various assumptions regarding the relation between measurements and their standard errors, and comes to the conclusion that when the error is proportional to the measurement the use of logarithms is likely to produce normal curves.

Testing Transformations

It is usually necessary to discover the best method of normalization by trial and error. Standard statistical methods such as the calculation of goodness of fit and moments give the ultimate criterion of the success of any particular method of normalization, but a simple graphical method indicates at once not only which transformations are successful, but also in what ways other transformations fail.

This graphical method consists in first applying the appropriate transformation to the observations and then plotting the results as abscissæ either on probability paper, or against probits as ordinates. The probit is best defined in terms of the normal equivalent deviation (N.E.D.). The N.E.D. corresponding to any given percentage is calculated from the shape of a normal curve the standard deviation of which is one ; it is the deviation (from the mean) equivalent to the given percentage of the area of the curve. The probit is equal to the N.E.D. + 5. This is now a standard technique[7] and need not be discussed in detail. It has been widely used in experiments on toxicity, when the data are obtained as a relation between the dose of a drug and the percentage mortality which it causes[8,9]. Each mortality is converted, by means of tables, to a probit. If the animals vary in such a way that the dose (or transformed dose) is normally distributed, the probit should bear a linear relation to the dose (or transformed dose). It is usually obvious at once whether the plotted points are distributed at random about a straight line ; and, if they are, it is possible with practice to draw a straight line which fits the results well enough for most purposes. Regression lines may be fitted if necessary, and it is possible to obtain the solution giving maximum likelihood by a suitable technique using successive approximations, which was discovered after less satisfactory methods had been used[10]. Any regular tendency for the points to diverge from a straight line shows that the distribution is not normal, and how it differs from the normal curve. The reciprocal of the slope gives an estimate of the standard deviation when the line is straight, and is proportional to the 'reaction' at each point when the line is not straight.

The primary use of this graphical method is where the data are limited to the percentages corresponding to different values of the variable (for example, dose); but the same method is sometimes helpful even when fuller information is available. If n observations have been made of a given variable, one method is to arrange them in order of size and then allot to the smallest observation a percentage of $100/2n$ and to succeeding observations percentages of $300/2n$, $500/2n$ . . . $(2n - 1)100/2n$. These percentages are then converted to probits and each individual observation is plotted. If the data are numerous they are grouped and added cumulatively, and the probits are plotted against the points separating the groups. When the number in a group is very small it is best to plot individual readings, or to assume that the observations are evenly distributed in the range covered by the group. If straight lines are obtained the distributions are normal, and the mean and standard deviation can be estimated fairly accurately from the graph. When results are treated in this way, the usual technique for calculating a regression line is inapplicable. The best estimates of the mean and standard deviation will be obtained by applying the ordinary methods directly to the transformed observations, but in some cases they can also be estimated from the moments of the original distribution. This is likely to be the most convenient method when the original observations are grouped, but its scope is limited. Examples are given below.

The use of probits also provides a general graphical method of normalizing distributions without the use of any formulæ. This may be useful when the scale on which the results are measured is a purely arbitrary one. If a random sample of observations is plotted against probits and a smooth curve is drawn through the results, this curve may be used for converting subsequent observations to a scale of probits, which are, of course, normally distributed. It is important in this case to be certain that the shape of the original curve and the variance of the transformed curve are stable. This principle has been applied by Ferguson[11,12] to the results of mental tests.

The Transformation $X = \log x$

The theoretical justification for using this transformation for most scientific observations is probably better than that for using no transformation at all. The general arguments in favour of it were discussed by Galton[13], who also directed attention to the fact that the normal law predicts negative observations. The existence of men of more than double the average weight implies the existence of other men with negative weight. When logarithms are used this difficulty does not arise.

When measurements are made of the size of a number of small objects of the same shape, it is often possible to measure either their diameters or their volumes. If the distribution of the diameters is normal, then the distribution of the volumes will necessarily be asymmetrical, and vice versa. The normal law cannot be true in both cases. The use of logarithms removes this difficulty[5]. If the logarithms of the diameters are distributed normally with standard deviation λ, the logarithms of the volumes will be distributed normally with standard deviation 3λ.

These theoretical arguments thus lead to the conclusion that this transformation should facilitate the interpretation of results when the variations are large ; when they are small it can at the worst do very little harm, since it has very little effect on the shape of the curve. The extra labour involved in converting the observations to logarithms to base 10 is small, though perhaps sufficient to deter those who deal with small variations. Mathematicians prefer natural logarithms, but experimenters usually prefer ordinary logarithms to base 10, and these give equally good results. The symbol λ is used[8] to denote the standard deviation of the logarithms to base 10.

One logical consequence of the adoption of this method would be that the mean of the logarithms, or the geometric mean of the observations, would be taken as the most likely value, instead of the arithmetic mean. Williams[14,15] obtained direct evidence of the value of this in experiments on the number of insects caught in a light trap. The use of logarithms had the double advantage of making the results more consistent and of preventing the result from depending almost entirely on one aberrant large catch. It is likely that this device would increase the precision of most experiments in which the variation is large.

If the original observations have been grouped on an arithmetic scale, the direct computation of th constants of the transformed distribution may be laborious. These constants can be calculated from the mean ($\bar{x}$) and standard deviation (σ) of the original distribution, but the estimates so obtained are only reasonably efficient when λ is less than 0·14[16]. In this region λ can be estimated within 3 per cent by dividing the coefficient of variation by 231. The general formulæ are

$$\bar{X} = \log_{10} (\bar{x}/(1 + \sigma^2/\bar{x}^2)^{1/2})$$
$$\text{and } \lambda^2 = 0\cdot4343 \log_{10} (1 + \sigma^2/\bar{x}^2).$$

Lognormal Distributions

It is proposed to call the distribution of x 'lognormal' when the distribution of $\log x$ is normal. Lognormal distributions have been discovered in many fields of work. Kapteyn[4] quotes the example of some data by Heymans on the threshold of sensation as measured by the smallest weight which was just perceptible on the skin. Wightman, Trivelli and Sheppard[17] found that the size of the particles of silver in a photographic emulsion were lognormally distributed. The diameters and areas of projection were measured, and it appeared at first that the form of the distribution of both measurements varied in different experiments. When the logarithmic transformation was used, normal curves fitted all the measurements of both diameter and area.

The distribution of sensitivities to drugs among individual animals of the same species, as measured by the dose required to cause some definite effect, has been widely studied. The sensitivity may vary over a tenfold range or more, but in practically every case the logarithm of the sensitivity is normally distributed or nearly so[8,18]. This fact, which is now generally accepted, has proved very convenient in the design of toxicity tests and in the calculation of their errors. The values of λ range from 0·014 to 0·91.

Similar methods have been applied to the action of disinfectants[19] and it has been found that the relation between time and the death-rate of bacteria can be explained, in some cases at least, on the theory that the logarithm of the survival time is normally distributed.

Hemmingsen[20] studied the distribution of the average size of the different species in each of various phylogenetic groups and found that they were distributed approximately lognormally ($\lambda = 0\cdot083$–$0\cdot673$).

Other examples of lognormal distributions have been found in estimates of the numbers of plankton caught in different hauls with a net[21], and in the amounts of electricity used in medium-class homes in the United States[22].

Bacteriologists have to deal with wide ranges of variation, as is illustrated by the data of Brew[23], who calculated coefficients of variation up to 640 per cent in bacterial counts. Such data can only be effectively treated by some such device as that discussed here, and bacteriologists often use a logarithmic scale.

Wechsler[24] collected a large number of data relating to measurements of human beings, and had trouble with their interpretation. The distributions were sometimes normal, but when the variation was large, the curves were skew with the mode less than the mean. He found that it was best to express the range of variation in terms of a ratio, and used for this purpose the ratio of the measurement on the 999th individual out of 1,000 to the measurement on the second individual. When there were less than 1,000 individuals, he was at a loss for a method of extrapolation and took the total range actually covered by the observations. The curves obtained are just the kind which are improved by taking logarithms. A number of the distributions studied by Wechsler are, as a matter of fact, lognormal, or approximately so, and there can be little doubt that their interpretation would have been facilitated by taking logarithms. The values for λ in some of these data have been estimated as follows: height, 0·015, 0·0164, 0·0172, 0·017; blood sugar, 0·029; weight, 0·045, 0·055; blood pressure, 0·049; pulse-rate, 0·061, 0·067. It will be seen that λ for weight is about three times λ for height, as is to be expected theoretically.

Cooper[25] made a number of measurements of the size of drops in emulsions. Some of his distributions were apparently complex, but in the only example for which details are given the diameters (and volumes) are distributed lognormally to a close approximation ($\lambda = 0\cdot17$ for diameter).

Cochran[26] discusses various transformations and comes to the conclusion that the logarithmic one is particularly effective, but that it makes no significant difference when the coefficient of variation is less than 12 per cent. He gives evidence that the standard deviation was proportional to the mean in measurements of the reaction time of human beings in a word test, and concludes that the distribution is likely to be lognormal.

Williams[15,27] has applied the same transformation successfully to data in which the variable was not an actual physical measurement but a count of the number of insects caught in a light trap, or the number of words in a sentence by G. B. Shaw.

Some of the effects of drugs on enzymes, and of oxygen on hæmoglobin, can be explained on the theory that the molecules of a protein in a solution show continuous variations among themselves, and that certain of their properties are lognormally distributed[28].

The Transformation $X = \log (x + x_0)$

If the probit is plotted against $\log x$ and the points diverge from a straight line, it is sometimes possible to find an explanation in such factors as a failure to allow for the mortality occurring when no drug is given, or a failure to count drops too small to be seen. In some cases it may be desirable to find a transformation giving a closer fit to the data than the simple logarithm. One convenient formula is

$$X = \log (x + x_0).$$

This is useful when the curve shows a more or less constant curvature, or with flat curves which diverge most at their lower ends. If the curve is convex upwards with probits as ordinates, x_0 is negative; if it is concave upwards, x_0 is positive. If a good fit is obtained, it suggests that the variations are proportional to the amount that the variable exceeds the value $-x_0$. If full data are available the constants of the curve can be estimated from the mean and the second and third moments of the original distribution[29,30]. Kapteyn[4] gives another method. A rough estimate of x_0 may also be obtained from a graph in the following way. Take three equidistant points on the scale of probits, such as 4, 5 and 6. Estimate from the curve the corresponding values of $\log x$ and thus of x. If these values are x_1, x_2 and x_3, then we wish to determine x_0 so that $(x_2 + x_0)$ shall be the geometric mean of $(x_1 + x_0)$ and $(x_3 + x_0)$, so that $(x_2 + x_0)^2 = (x_1 + x_0)\ (x_3 + x_0)$, or $x_0 = (x_2^2 - x_1\ x_3)/(x_1 + x_3 - 2x_2)$. The success of this correction can be tested by plotting $\log\ (x + x_0)$ against probits. For extrapolation at one end of the curve it may be convenient to choose x_1, x_2 and x_3 near that end.

This transformation has been fitted to observations of the value of house property and of the size of the foreheads of crabs[4], the ages of employees of a commercial firm and the number of petals on a buttercup[29] and the weights of female students[30]. The curves obtained in this way fitted the observations better than formulæ obtained by the methods described by Pearson.

Curves of this type can be fitted to measurements recorded by Nagelschmidt[31] of the diameters of particles of airborne dust in coal mines. In some cases the distributions appear lognormal ($\lambda = 0{\cdot}2$–$0{\cdot}4$), but in others the curves obtained when probits were plotted as ordinates against log diameter were concave upwards. When the transformation $X = \log\ (x + x_0)$ was used, the calculation of χ^2 showed that the fit was good.

Williams[15] used this transformation with $x_0 = 1$ in order to avoid complications in calculating the geometric mean when $x = 0$. This only affects the shape of the curve for small values of x.

Conclusion

If it were the normal custom, when scientific observations show uncontrolled variations large compared with the observations themselves, to convert them to logarithms before estimating their mean or variance, the usual result would be an increase in the accuracy and scope of the conclusions drawn from them.

NEW VIEWS OF THE ORIGIN OF THE SOLAR SYSTEM

By Prof. W. H. McCREA

Royal Holloway College, University of London

THE field is still open for the formulation *de novo* of theories of the origin of the solar system. No observational test has ever been discovered which would impose a definitive restriction upon the basic possibilities, as, for example, to show whether or not we must look to some catastrophic event to produce the necessary initial conditions.

Interest in the problem has recently been revived by attempts to approach it afresh along three totally independent lines. Von Weizsäcker[1] proposes what amounts to a re-instatement of the nebular hypothesis, with the incorporation of several novel features; Alfvén[2] makes the radical suggestion that it was the magnetic field of the sun which governed the manner in which it acquired the material of the planets from interstellar space; Hoyle invokes a nova outburst as a catastrophic origin of this material. None of these theories can as yet claim completely to demonstrate that a planetary system must inevitably have resulted from its postulated initial conditions. But they all offer apparent explanations of some or other of the general characteristics of the actual planetary system. In spite of their diverse approaches, it is not impossible that further progress may be made by combining ideas drawn from more than one of them*.

At the same time, thanks to suggestions by Jeffreys and others, the idea is gaining ground that the basic agency in the formation of the solid substance of planets may be no more than the most common form of condensation from a vapour to a solid. This may prove to be a simplifying factor in the whole problem.

Weizsäcker's Theory

Weizsäcker's theory belongs to the class of those which seek the origin of a planetary system in a rotating nebulous envelope around an already existing sun. His fundamental hypothesis is that the chemical composition of the envelope was initially the same as that of the sun itself. Since the chemical composition of the present planets is very different (comprising a bigger proportion of the heavier elements) they can then represent only a fraction of the original mass of the envelope. Weizsäcker takes this fraction to be as low as one per cent. For he accepts a recent estimate by Biermann[3] for the composition of the sun, which gives it a much higher content of the lighter elements than is currently assumed. In this manner he proposes to overcome the difficulty, encountered by older theories of this class, that the initial density of the envelope would have been too small to lead by the ordinarily recognized gravitational processes to condensation into planetary bodies. At the same time, through the dissipation of the surplus 99 per cen composed of light elements, he proposes to accoun for the disappearance of an embarrassing amount o angular momentum.

Weizsäcker envisages several stages in the evolution of his system, each of which he investigates in detail. But it has to be said that the way in which i is conceived to pass from one stage to the next involves a number of obscurities.

---

* The meeting of the Royal Astronomical Society on July 13, 194 was devoted to a discussion of these theories, which were outline respectively by the present writer, Dr. A. Hunter, and Mr. F. Hoyl Subsequent speakers were Prof. H. H. Plaskett, Prof. S. Chapma Dr. H. Jeffreys, Dr. G. P. Kuiper and others. This article is a dige of what was said, with some slight additional commentary; it do not treat other recently proposed theories not included in the di cussion, such as that of J. B. S. Haldane, *Nature*, 155, 133 (1945).

The envelope is considered to have been acquired in some relatively dense part of the general interstellar cloud. Since the latter was presumably in a state of turbulence, the first picture of the envelope is of an aggregate of portions of gas and dust particles moving n more or less independent orbits in the sun's gravitational field, the planes of the orbits being orientated in a haphazard fashion. Assuming a non-zero resultant angular momentum, the first effect of viscous interactions between the parts of the system is to bring them into nearly circular orbits in or near the plane through the sun normal to the axis of this momentum. This produces a flattening of the envelope; Weizsäcker estimates its resulting second stage to be approximately a disk of diameter about equal to that of the present solar system and thickness rather less than one-hundredth of this, the emperature of the material at any point being about the same as a planet there would possess at the present time.

By virtue of the orbital motions, the angular velocity of the material about the sun decreases outwards. The next effect of viscosity is to tend to equalize the angular velocity throughout. Now there is a familiar argument which appears to show that this results in a dissipation of the material, and such, fundamentally, s the process by which Weizsäcker disposes of his excess material. The argument, however, is one which Jeffreys has shown to be unsound, the actual effect of viscosity in such a system being mainly to cause the material gradually to ooze into the central body. Nevertheless, this in itself does not necessarily vitiate Weizsäcker's further inference that viscosity must produce turbulent convection currents in the material.

Weizsäcker argues that if the viscous forces are ufficiently small we should expect these currents to build up into some regular pattern. The endeavour to discover such a pattern is the central part of his whole work. He eventually proposes one consisting of a series of rings of large-scale 'vortices' moving with etrograde circulation between concentric circles long which there are trains of small turbulent eddies possessing direct rotation. In the 'vortices' themelves, turbulence is almost negligible and the eddies erve somewhat as 'ball-bearings' between them. A quantum condition' that an integral number of vortices should just fill each ring, coupled with ertain conditions concerning the stability of individual vortices, requires the radius of the *n*th circle of the set to be proportional to 2^n.

Finally, Weizsäcker believes that the eddies must come together, and that this behaviour leads ultimately to the formation of planets by a mechanism of ccretion. This way of locating the formation of anets gives satisfactory agreement with Bode's w concerning their distances from the sun. The act that it does so is claimed by Weizsäcker as evidence for the occurrence of the whole process. He then ds scope in the theory for the production of satellites.

The pattern of 'vortices' may in itself possess all e properties that Weizsäcker ascribes to it. But it founded upon a set of gravitational orbits which nstitutes an extraordinarily special selection from among those of any random aggregate of such orbits. fact the selected set possesses certain characteriss the reverse of the statistical ones of a random set. it is exceedingly hard to conceive how it could turally have arisen from any earlier state of the system. It is therefore scarcely to be expected that the theory will survive in anything like its present form. Its value will probably lie rather in stimulating a re-examination of many aspects of non-catastrophic processes which could have had some part in the formation of planets.

Alfvén's Theory

This theory, like the preceding one, supposes that the raw material of the planetary system was collected by the sun from interstellar space, but it makes everything depend upon the mechanism by which this was achieved. Alfvén's suggestion is briefly this: The sun was rotating and possessed a dipole magnetic moment; neutral atoms fell towards it under gravitational attraction until their motion became thermal owing to collisions and produced ionization; electromagnetic forces on the ions in the magnetic field overwhelmed gravity and prevented their falling further; the trajectories in the magnetic field led to an accumulation of ions in a thin layer near the sun's equatorial plane; there they once again became neutral and so acquired gravitational orbits; the planets then emerged as a result of a mode of coalescence described by Lindblad[4]. More precisely, this process is thought to have produced the major planets, while a similar one applied to dust-particles instead of gaseous atoms gives the others. The process necessarily involves a transfer of angular momentum from the sun to the captured material.

The fundamental difficulty of this approach is the question as to whether the sun can in fact possess the requisite unshielded magnetic field. A possible view is that its general field is inappreciable outside its own atmosphere, though it has been suggested that there may be slight evidence to the contrary in some observed features of comets' tails. Further, many questions concerning the production of the ions and concerning their mean free paths demand closer investigation than Alfvén has yet given.

So the situation is that, while electromagnetic effects would be of over-riding importance in the early stages under the conditions imagined by Alfvén, the realization of those conditions is still far from being an established fact. But his work does at least demand that, in the sort of re-examination contemplated at the end of the preceding section, the possibility of electromagnetic effects must be thoroughly investigated.

There are also points regarding the later stages which are not elucidated by Alfvén's work. For example, though it yields a density distribution which would give fairly correct relative masses of the planets were the material divided up at appropriate distances from the sun, it provides no clue as to why this particular division should in fact occur.

Hoyle's Theory

Hoyle believes that the difficulty of accounting for the mere quantity of material in the planets, if it is supposed to have been gathered from interstellar space, is more serious than the preceding theories allow. He therefore reverts to the hypothesis of a stellar, rather than interstellar, source of material. But instead of the more customary assumption that it was pulled out by a collision, he suggests that it was pushed out during a nova outburst. He cites the case of the Crab Nebula as showing that such a process can certainly involve a plentiful supply of potential raw material: since it started as a supernova in A.D. 1054, an estimated quantity amounting to about fifteen times the mass of the sun has been ejected. In such a case the material comes away with very high velocities. But Hoyle asks what would have happened had the original star been a binary.

Suppose the sun had at one time possessed a companion at about the distance of Jupiter, and suppose this companion became a nova. The ejected matter might not then come off with complete isotropy, so that the nucleus of the nova might have been knocked out of the system. When the outburst was dying down, some of the ejected matter may have had insufficient energy to escape from the gravitational field of the sun. This is Hoyle's suggested source of material for the formation of planets; the captured material need represent only a modest fraction, perhaps of the order of 10^{-4}, of the total ejected matter. The resultant angular momentum is regarded as traceable to the original orbital motion of the binary. However, the idea is so far only in tentative form; its author will no doubt shortly provide a fuller discussion.

Condensation Processes

Hitherto, gravitation has usually been thought of as the fundamental agency responsible for the condensation of nebulous matter into planetary bodies, either by causing a cloud of such matter to collapse upon itself under its own gravitation, or else by aiding accretion by causing particles of a cloud to fall towards an incipient planet passing through it. Jeffreys[5] has, however, recently posed the crucial question as to whether gravitation is the only important agency in producing condensation. The commonest process of condensation with which we are familiar is that represented by a raindrop. Is it possible that this process plays a part in the formation of a planet? The actual form of the process would be more like that which occurs in the production of a snowflake, condensation being directly into the solid state. The only criterion as to whether it will take place is that the partial pressure in the surrounding gas should exceed the vapour pressure of the solid. The necessary figures for the vapour pressures of planetary matter in the solid state are difficult to come by; but Parson[6] has given estimates according to which the criterion is likely to be satisfied at the kind of temperature to be encountered at, say, the distance of Jupiter even for existing pressures there.

The merit of such condensation as the key to the production of planetary material is that it can proceed in much less specialized conditions than the elaborations of the various theories are designed to provide. It is, in fact, fundamentally equivalent to an earlier suggestion by Lindblad[4].

Some indication of the validity of these ideas may be found in the fact that there are in the solar system small bodies, the density of which is less than that of any known solid. Jeffreys's suggestion is that such a body may be a loose agglomeration of crystals which have grown by this process of condensation—that the body possesses, in fact, the structure of a large snowball.

REACTIONS AT INTERFACES AND THEIR SIGNIFICANCE IN BIOLOGY

By Dr. J. F. DANIELLI
Department of Zoology, University of Cambridge

IN his Liversidge Lecture before the Chemica Society, on "Reactions in Monolayers", Prof E. K. Rideal made the most comprehensive survey yet available of studies of chemical reactions i monolayers. This is a field of chemistry which ha recently become of exceptional interest to th biologist, so much so that the cell physiologist canno afford to be ignorant of the progress which has bee achieved in the last fifteen years; this is all th more remarkable in that thirty years ago this aspec of chemistry, practically speaking, did not exist.

It has, of course, for long been realized tha reactions at interfaces present peculiar features, an that some of these may be of great importance i biology. F. G. Donnan laid emphasis on the import ance of surfaces in biology when giving the fir Liversidge Lecture. But before biologists could begi to consider these theoretical possibilities in relatio to their special field it was requisite: first, that tech niques should be devised capable of dealing with th surface properties of molecules of types of biologica interest; and secondly, that an exploration shoul be made of the types of reaction and behaviou particularly characteristic of molecules at interface The first of these steps was to a large degree accom plished by the early nineteen thirties, but the secon phase was barely commenced. N. K. Adam ha made some studies of hydrolysis of lactones in mon layers, and of the oxidation of cholesterol monolayer which were highly suggestive. To-day a substanti part of the field has received a preliminary survey largely embodied in reports from Prof. Rideal's ow laboratory, and, though only parts of the field ha been touched, it is already apparent that it will yiel results of the greatest value to biologists.

From a theoretical point of view, the importan of this field is sufficiently emphasized if we consid some of the reactions involving the common maj components of living tissues—fats, proteins, nucle tides and carbohydrates. The great majority of t natural fats are so insoluble in water that the reactivity as individual molecules in aqueous soluti can be neglected. The final steps in their synthes and the initial steps in their utilization, must occ either in the interior of a lipoid phase or at a lipoi water interface. The enzymes catalysing the reactions are insoluble in lipoids, so that the reacti site is limited to interfacial regions. The same is tr of the steroids. The proteins are thought by so to be synthesized as polypeptide chains adsorbed oil-water interfaces, and to acquire specific chara teristics as globular proteins by processes occurri on desorption. Whether this be so or not, it is cert that a protein molecule, in the later stages of synthesis, itself constitutes a moderately well-defin interface, in the vicinity of which any further sy thetic or degradative reactions must occur. Final the enzymes catalysing the reactions affecting fa steroids, proteins, nucleotides and carbohydrates themselves such large molecules that the reacti they catalyse are in fact occurring at the surface the enzymes, that is, at an enzyme-water interfa and in no sense in a homogeneous solution. In bri it is fair to say that the present state of knowle indicates that the vast majority of the chemical reactions occurring *in vivo* are reactions occurring at interfaces, and moreover at interfaces resembling in type those which can be explored by present-day surface techniques.

That chemical equilibria at interfaces would be different from those in homogeneous solution was suggested by J. J. Thomson (1888), in his work "Application of Dynamics to Physics and Chemistry". Much attention has from time to time been devoted to the study of this principle, and H. Freundlich (1930), when giving the second Liversidge Lecture, brought together many striking examples of this phenomenon. We now know that interfacial regions differ from the homogeneous phases with which they are in contact in many particulars: the *p*H, ionic strength, oxidation-reduction potential and the ratio of univalent to polyvalent ions at an interface may all differ substantially from their values in the surrounding bulk phases. In addition to these differences, molecules diffusing into the interface will often be subject to special forces produced by the orientaion of molecules at the interface, as a result of which unusual concentrations and juxtapositions of paricular chemical groupings may arise, and to a sharp electrical potential gradient in the interfacial region produced by the oriented polar groups of the interfacial molecules. Some of the effects of these peculiarities of interfaces may be demonstrated by very simple experiments. Deutsch (1929) showed hat if an aqueous solution of a *p*H indicator is shaken with a little liquid hydrocarbon, a marked colour change will occur if the *p*H of the aqueous olution is in the region in which the indicator is sensitive. The colour change produced by shaking is aused by adsorption of indicator on to the surface of the emulsified hydrocarbon, and is quite reversible, he original colour returning as the emulsion breaks. The change in colour on adsorption is produced by a shift in chemical equilibrium subsequent to adsorpion. Later studies have shown that the shift is mainly caused by the fact that the *p*H in an interacial region differs from that in the surrounding bulk phases. The colour shift shown by this experiment of Deutsch is in some ways allied to what is commonly known as the 'protein error' with *p*H indicators. When *p*H indicators are added to aqueous solutions of proteins, the colour produced may indicate a *p*H differing by more than a *p*H unit from the true value, given by a glass electrode. This 'error' has been shown to be produced, in part at least, by the fact that the *p*H at the surface of a protein molecule is substantially different from that of the bulk aqueous phase in which the protein is dissolved. When the indicator is adsorbed, it of course tends to react to the interfacial *p*H, not to the bulk *p*H.

A similar displacement of equilibrium is observed a monolayer of palmitic acid is spread upon a solution of sodium and calcium acetate. If the sodium : calcium ratio in the acetate solution is 00 : 1, we might perhaps expect to find a similar atio in the monolayer. But when the monolayer is wept off the solution and analysed, it is found that here is rather more calcium than sodium in the monolayer! This phenomenon lies behind the efficiency of calcium as an antagonist of the detergent ction of soaps, and is likely to be concerned in etermining the so-called 'physiological ratio' of odium to calcium. For normal physiological ehaviour of a tissue it is usually necessary that the fluid bathing it should have a sodium : calcium ratio of the order of 100 : 1. That one calcium ion should be competent to balance the action of a hundred sodium ions is inconceivable; but if, as we now believe, the site of action of the ions is a surface, and at this surface rough equality of concentration and balance of action of sodium and calcium is produced by a bulk ratio of 100 : 1, then we have a reasonable explanation of the importance of the physiological ratio of this order.

Experiments such as those just mentioned are not those with which Prof. Rideal was particularly concerned, but formed part of the background of less specific factors against which the review of more specific factors given in his lecture must be viewed. By using the special techniques of surface chemistry, he and his colleagues have been able to study many details of behaviour of the molecules which are more permanently fixed at an interface. For example, it has been shown that the velocity with which a molecule in a monolayer will react with a constituent of the bulk solution is a function of the closeness of packing of the molecules; the closer the molecules are together, the more slowly they react with the bulk phase component. This is true of the hydrolysis of lactones and esters by hydroxyl ions, and of the oxidation of unsaturated fatty acids by acid permanganate solution. Compression of a monolayer of such substances affects the rate of reaction by changing both the energy of activation and the steric factor, as may be shown by the case of the hydrolysis of trilaurin by hydroxyl ions: when the surface pressure, that is, the force compressing the monolayer in the two dimensions of the surface, is raised from 5·4 to 16·2 dynes/cm., the activation energy is raised from 10,100 to 15,100 calories, while the steric factor increases from $1 \cdot 1 \times 10^{-6}$ to $4 \cdot 1 \times 10^{-2}$. The velocity of hydrolysis of esters in monolayers is also affected by the orientation of the different parts of a molecule with respect to one another. Cetyl palmitate takes up one type of configuration giving a velocity constant of 0·18 min.$^{-1}$ under a given set of conditions, whereas ethyl palmitate, taking up a quite different configuration at an interface, has a velocity constant under the same conditions of 0·005 min.$^{-1}$. Prof. Rideal points out that there is some degree of parallelism between the phenomena observed when esters in monolayers are hydrolysed by hydroxyl ions, and those observed when the enzyme lipase is the catalytic agent. It would be of great interest to see such studies extended, though a pre-condition for analysis of the enzyme studies may perhaps be the isolation of pure lipase, which has not yet been achieved. But even the present state of investigation is of interest and assistance to the biologist in the formulation of working hypotheses concerning the control of enzymic reactions. One of the central problems of the cell physiologist is to discover the mechanisms whereby the rates of enzymic reactions are adjusted to suit the needs of the organism. It is common for enzyme and substrate to exist in the same cell, apparently in close proximity, and yet no net reaction will proceed until a particular phase of physiological activity is embarked upon. The influence of surface pressure on reaction velocity indicates one means whereby a reaction may be held in abeyance until required.

Another phenomenon of great interest to biologists is the formation of molecular complexes between molecular types such as fats, steroids, phospho-lipins, proteins and lytic molecules. Monolayer techniques form an unusually elegant means of studying these complexes. When a second substance is injected into the aqueous solution underlying a monolayer of a pure substance, a large increase in surface pressure is found if complex formation occurs accompanied by penetration of the second molecular species into the monolayer. If the reaction is between polar groups only of the two molecular species, there may be no change of surface pressure, but there will be a change in the electrical potential across the film. If there is no complex formation of any type, no change in either surface pressure or potential occurs. Complex formation of the type revealed by these surface techniques has been shown to be of importance in the mechanism of red cell lysis, and in the permeation of some membranes by such substances as phenols. For example, the penetration of hexyl resorcinol into *Ascaris lumbricoides*, according to Trim and Alexander, may be accelerated by a factor of about fourfold by adding low concentrations of detergents, with which the resorcinol forms complexes. The mechanism of this acceleration is not yet understood, and may well repay detailed study.

Interesting complexes are formed between some carotenoids and certain proteins. Astaxanthin exists in the eggs and integument of lobsters, crabs, etc., as a blue-green pigment. The carotenoid is readily oxidized to astacene in the dead animals. When the association between carotenoid and specific protein breaks down, a colour-change ensues. The association may be destroyed by boiling, which denatures the specific protein, or by addition of sodium soaps. In the latter case, the change is reversible, restoration of the original complex being achieved by addition of calcium (Peters and Wakelin). Visual purple also appears to be a complex of this type, namely, protein-carotenoid. One theory of the action of light upon visual purple is that it oxidizes a termina CHOH group of a polyene chain to the corresponding aldehyde. Monolayer studies show that on conversion of a CHOH group to a CO group, a large change of surface potential occurs. It is therefore possible that, if the carotenoid of visual purple also forms part of the lipoid layer of the cell membrane the photo-oxidation will produce a change in surface potential sufficient to cause electrical excitation o the cell. These relationships are at present all highly speculative, but it is in harmony with recent developments in cell physiology to adopt the working hypothesis that the stimulation of retinal cells by light is produced by a surface photo-oxidation of the visual pigment incorporated in the cell membrane and that the change in surface potential produced by this reaction temporarily discharges the resting potential of the cell, causing an electrical response.

These reflexions on the topics of Prof. Rideal's lecture show that a pathway for investigation of many biological problems has already been secured by the study of reactions at interfaces. So numerous are these possibilities that the rate of investigation o these fields is likely in the immediate future to be determined almost entirely by the number of investigators available; all such investigators will find a source of inspiration in Prof. Rideal's lecture.

OBITUARIES

Prof. Ernest Shearer

A NATIVE of the island of Stromness in Orkney, Ernest Shearer was brought up to farming; but he could also sail a boat and follow the maritime pursuits of his Viking ancestry. A 'lad of parts', he was thoroughly schooled in mathematics and classics and went on to the University of Edinburgh where, between 1897 and 1904, he studied and graduated M.A. with honours in economics and B.Sc. in agriculture. His first appointment was to the Indian Agricultural Service, where in five years he reached the grade of assistant inspector-general. In 1911 he was appointed under the Egyptian Government as principal of the Giza Higher College of Agriculture and in 1919 he was made chief technical officer in the Egyptian Ministry of Agriculture.

In 1924 Shearer accepted the post of principal in the Edinburgh and East of Scotland Agricultural College; two years later he was made professor of agriculture in the University, thus becoming the first head of the Edinburgh School of Agriculture. During his tenure of office the proper utilization of land and the teaching of young farmers became more and more of national importance, and he rose to eminence as an authority on agricultural education. He reached this position by reason of his training and experience, but also because of inclination, for he had a great interest in, and sympathy for, young people. When he retired from his academic posts in the autumn of 1944 he became secretary to the Mid and East Lothian Agricultural Executive Committees, and thus continued to serve the farming community until the time of his death.

Shearer was a large and genial man, entirely fre from affectation, with a strong sense of humour and great personal charm. Completely at ease in an situation, he would pass an hour as happily with his gardener as with his fellows on the Senate. He handled a brilliant pen and possessed great strengt of character and determination. Not only was h thus well qualified for leadership but he could als be relied on to fight for any right cause and to stan like a bulwark in the interests of his people.

His hobby was the propagation of fine fruits an beautiful flowers. He had planned to retire to h beloved Orkney and to devote himself to the production of plants which would bring both ameniti and profit to the island farmers. His untimely deat is, therefore, as much a loss to his native land as is a grievous blow to his friends and colleagues.

J. A. MORE.

Mr. L. E. Adams

LIONEL ERNEST ADAMS, who was well known to a earlier generation as an active and enthusiast observer of the natural history of the British Isle died at Ryde, Isle of Wight, on September 20, at t age of ninety.

Adams was the nephew of Henry and Arth Adams, famous in their day for their researches the molluscs, and joint authors of "The Genera Recent Mollusca". Circumstances did not allow hi to follow his uncles' wider sweep, and he had confine himself to the British land and freshwat species, on which he became an authority of reput

In 1884 he published "The Collectors' Manual of British Land and Freshwater Shells" with coloured plates drawn by his brother Gerald, but the figures of *Pupa* and *Vertigo* (Pl. vii, Figs. 10–22) prove that the author himself was no mean artist; a second edition appeared in 1896. Apart from this one book, Adams published many notes and papers in various natural history journals, especially in the *Journal of Conchology*. Most of these dealt with the habits of the animals, and were precursors of the ecological studies so fashionable to-day.

The native mammals of Britain attracted him strongly, and on them he spent much of his energy. The most widely known of these researches is that on the 'fortress' of the mole. After digging out no fewer than three hundred of these structures, Adams was able to show that not one of them was like the familiar figure derived from Blasius and Geoffroy St. Hilaire, which had been copied by one or another writer of popular works for more than a hundred years.

Even this did not exhaust Adams's activities. There was scarcely a group of invertebrates from earthworms to woodlice which he did not collect at some time or other, either on his own behalf or because he knew that someone needed the material for study. In the field he was a lively companion, a noted teller of stories; as a correspondent he was prompt and accurate, ready to pass on all the information at his disposal. A. T. HOPWOOD.

WE regret to announce the following deaths:

Prof. George R. Gage, professor of botany in Vanderbilt University, Nashville, Tennessee, on August 18, aged fifty-five.

Mr. C. F. Dendy Marshall, a founder member and past-president of the Newcomen Society and an authority on the early history of railways, on June 14, aged seventy-two.

NEWS and VIEWS

Biochemistry at University College, London: Prof. F. G. Young

PROF. F. G. YOUNG is relinquishing his chair at St. Thomas's Hospital Medical School to succeed Sir Jack Drummond as professor of biochemistry at University College, London. In so doing, Prof. Young will be renewing a long association with University College, of which he was an undergraduate in the honours school of chemistry; for, in addition to receiving his early training there, he was successively (1929–32) Bayliss-Starling Scholar in biochemistry, Sharpey Scholar and Shafer Prizeman in physiology. After holding Beit Memorial fellowships for medical research, Prof. Young then gained further experience by serving as honorary research assistant in the Department of Physiology, Aberdeen, and research associate, Department of Physiology, Toronto, returning to University College in 1934 as honorary assistant in the Department of Biochemistry. Two years later he joined the scientific staff of the Medical Research Council, on which he stayed until his appointment to the chair at St. Thomas's Hospital Medical School in 1942.

Prof. Young has already established an international reputation for himself by his research work. Commencing with the intermediary metabolism of carbohydrates, he was led naturally to the study of the diabetogenic action of extracts of the anterior pituitary and later to other activities of this gland. With Folley he published an important contribution upon the lactogenic hormone which led to further studies with Folley and others on the galactopoietic action of pituitary extracts. It is, however, in the sphere of carbohydrate metabolism that Prof. Young's chief interest has resided and in which his most numerous contributions have been made. In addition to his great activity as a research worker, Prof. Young has also given generously of his time to the Biochemical Society, which he served as joint secretary during 1938–42. In this year he was elected chairman of the editorial board of the *Biochemical Journal*, and the high standard maintained by that journal is an eloquent tribute to the success of his vigorous leadership. Prof. Young will carry the good wishes of all his colleagues with him to University College.

Prof. John Yudkin

DR. JOHN YUDKIN, whose appointment to the chair of physiology at King's College of Household and Social Science (University of London) has recently been announced, takes with him from Cambridge a high reputation as an experienced and successful teacher. Since 1934 he has been supervisor in biochemistry and physiology at Christ's and Emmanuel Colleges, and since 1940 director of medical studies at Christ's. He is also distinguished as an investigator with wide interests in several fields of biochemistry and nutrition. Possessing a particular regard for the social implications of nutritional knowledge and its application in public health, he has shown much organizing ability in the planning of various nutritional and dietary surveys. Dr. Yudkin entered Christ's College with an open scholarship in 1929 and graduated in 1931, after taking biochemistry in Part 2 of the Natural Sciences Tripos. He was awarded the Benn Levy Research Studentship in 1933, and for some years was engaged in research at the School of Biochemistry and the Department of Colloid Science, Cambridge, on problems relating to bacterial enzymes, with special reference to the mechanism of adaptation and variation. In 1936 he interrupted his research work temporarily in order to complete his medical qualification; he received the Letheby Prize in pathology at the London Hospital.

Since 1936 Dr. Yudkin has specialized in nutritional investigations, and has been attached to the Dunn Nutritional Laboratory, Cambridge, where he has held successively a Grocers' Scholarship and a Halley Stewart Fellowship. He is author, or part author, of some twenty publications on the subject: the topics in which he has been specially interested including, *inter alia*, vitamin B_1 metabolism; dark adaptation and slit-lamp microscopy; dietary and nutritional surveys on school children and factory workers; and feeding tests with vitamins and other supplements. He joined the R.A.M.C. in 1943, being first attached to the R.A.M.C. College in London, and later as pathologist to the West African Forces, Sierra Leone, and has published a number of papers from both these centres.

Naval Research and Development

Dr. C. F. Goodeve, the first holder of the post of deputy controller for research and development in the Admiralty, has left the department to take up the directorship of the British Iron and Steel Research Association. The post of assistant controller for research and development was instituted in 1942 and the status of the post has since been raised to that of deputy controller. The holder not only helps the controller of the Navy in supervising the application of science, technology and design engineering in the large range of departments which work under his superintendence, but is also adviser to the Board on research and development generally. Before Dr. Goodeve was appointed to this post he had been for some time previously associated with the Admiralty as an R.N.V.R. officer.

The new deputy controller for research and development is Mr. A. P. Rowe, who has during the War been head of the largest radar research establishment in Britain, the telecommunications research establishment at Malvern. This establishment, under the Minister of Aircraft Production, has been responsible for the research and design of the radar equipment both of the R.A.F. and the Fleet Air Arm. Mr. Rowe's connexions with defence research work go back to 1922, when he first joined the scientific staff of the Air Ministry.

Terrestrial Magnetism and Atmospheric Electricity

The present year, 1945, will mark the completion of the fiftieth year of the quarterly publication, *Terrestrial Magnetism and Atmospheric Electricity*, the foundation of which by L. A. Bauer in 1896 was a step of far-reaching importance for the progress of the sciences named in its title. It provides a most valuable focus and forum for them, and for border subjects related to them, such as sunspot and ionospheric studies. Though the editorial and financial responsibility for the periodical has always been American, in the hands of its two successive editors, L. A. Bauer (1896–1932) and J. A. Fleming (1928 to date), the periodical is international in the sense that foreign associates have been and are linked with the responsible editors, and can advise or make suggestions either when requested or on their own initiative; and also that suitable contributions from all countries have been welcomed and have provided a considerable share of the matter printed. Moreover, though most of the papers are printed in English, and always have been, papers are invited also in French, German and Italian. The pages of the fifty volumes well mirror the great progress that has been made in these branches of geophysics during the half-century, and the printing and production have been maintained at a high standard from the outset, and throughout the war years. The subscription-rate, 3.50 dollars per year, is less than double that of 1896, and is remarkably low for a periodical of its size and excellence. The best wishes of the Editors and of many of the readers of *Nature* will be with the direction of *Terrestrial Magnetism* as it begins its second half-century next year.

Science and Development in Australia

The John Murtagh Macrossan Memorial Lectures delivered to the University of Queensland by Sir David Rivett on June 13 and 15, 1944, on "The Application of Science to Industry in Australia", have now been published (Brisbane: University of Queensland. Pp. 48). Sir David, while emphasizing the importance of the international exchange of ideas and thought and of traffic in the products of the experimental laboratory and of the original mind, points out that some decrease in the international to-and-fro movements of products of soil and factory, and in particular a diminished demand overseas for Australian primary products, may be expected, and may even be desirable, to eliminate unnecessary transport. Distribution, he suggested, has become once more a main factor in Australian economy; if we look after consumption, both in quality and in quantity, production will look after itself. That involves basing industrial life on the best human knowledge that is available or ascertainable; and if industrial activity in Australia is to be much more diversified, some general ideas as to the main lines of development and the place of scientific effort in that development are essential. We must think in advance so far as possible in a democracy; but we should do so with the clear understanding that the divergent phenomena of which all plans concerned with human relations have to take account make most plans nothing more than intelligent guesses as to the best justifiable and possible courses. As such they should, like any other hypothesis of the scientific worker, be discarded or amended when the facts prove such treatment to be necessary.

With regard to primary resources, Sir David Rivett believes that Australia should find more consumers within her own borders, these consumers making other products required in return. The building up of secondary industries is imperative, and Sir David referred particularly to shipbuilding and the aircraft industry, light metals and alloy steels for these and other transport purposes, including the motor-car industry, the manufacture of goods for the electrical industry, building materials, household accessories, organic chemicals from alcohol, coal and carbide, engineering, the prepared food industry and mineral industries from the raw material to the finished product. Not more than 200,000 out of every million people would be required to supply that million with foodstuffs and clothing by Australian standards, and the remaining 800,000 should be absorbed in such secondary industries. Such development will only be possible if the universities of Australia are adequately developed and take their full place in fundamental research. National laboratories will be required for such work; but science must not be regarded as just the handmaid of industry. Industry should attend to its own scientific housekeeping, and the national laboratories and the universities should be given the utmost freedom to prosecute fundamental research. Urging the importance of education as a factor in industrial development, he referred finally to the problem of the impact of society upon science: the outstanding problem, he believes, is the handling of our present and coming powers so that their enormous possibilities for the good of humanity will be realized and applied to the total exclusion of any deliberate pursuit of evil aims.

Scientific Rehabilitation in Europe

Prof. G. I. Finch, professor of applied physical chemistry in the Imperial College of Science and Technology, is visiting Belgium and Holland to convey the greetings of the Royal Society on behalf of the men of science of Great Britain to their colleagues in those countries. The purpose of his visit is to renew and re-establish scientific contacts and to see what help can be given by British science towards the rehabilitation of science and scientific education in these two countries. In Belgium, Prof. Finch will be the guest of the Académie Royale des Sciences, des Lettres et des Beaux-Arts in Brussels, and in Holland he will be the guest of the Koninklijke Akademie van Wetenschappen.

Prof. I. M. Heilbron, professor of organic chemistry in the Imperial College of Science and Technology, and Dr. L. H. Lampitt, who are chairman and secretary of the British National Committee for Chemistry, have left on a visit to Paris to re-establish contact with French men of science. They hope to discuss informally the revival of international collaboration in science.

Nova Tamm

A TELEGRAM from Copenhagen announces the discovery by Dr. Tamm of a nova in the constellation of Aquila. It is thought that the nova will be named after its discoverer. On August 28, the date of its discovery, its visual magnitude was about 7 and its photographic magnitude 8·5. It was stated that there was a strong continuous spectrum with emission lines.

Dr. W. H. Steavenson observed the nova and gave more precise co-ordinates than those originally supplied. Its position, according to Dr. Steavenson, is R.A. 19h. 16m. 31s., Dec. + 0° 31·6′; equinox 1945·0; comparison stars + 0·4173° and + 0·4178°. Dr. Steavenson observed the nova on August 31 and found that it was pure white to the eye. Numerous bright lines in the spectrum, especially in the green and blue regions, were seen. He estimated the magnitude (visual) as 7·9. A later communication from Copenhagen states that the photographic magnitude originally given was very inaccurate. On August 30 it was 7·6. The position of the nova is now given as R.A. 19h. 16m. 30·64s., Dec. + 0° 31′ 45·4″.

Announcements

THE Lord President of the Council has appointed Prof. H. Munro Fox, professor of zoology in the University of London (Bedford College), Prof. I. M. Heilbron, professor of organic chemistry in the Imperial College of Science and Technology, London, and Dr. C. C. Paterson, director of the Research Laboratories of the General Electric Co., Ltd., to be members of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research from October 1. Prof. A. V. Hill, Sir Felix Pole and Sir Robert Robinson retired from the Council on completion of their terms of office on September 30.

THE Council of the Institute of Welding has awarded the Sir William J. Larke Medal for 1945, together with a first prize of £50, to Mr. W. K. B. Marshall of the Aluminium Plant and Vessel Co., Ltd., for a paper entitled "The Fabrication of Aircraft Fuel Tanks in Aluminium Alloy containing 5% Magnesium". The second prize has been awarded to Mr. J. Corston MacKain, of Redpath Brown and Co., Ltd. A third prize was awarded to the late Mr. H. W. Clark, formerly assistant engineer (bridges and structures) to the London Passenger Transport Board; Mr. Clark was the winner of the Medal in 1944. The fourth prize goes to Mr. R. W. Arden, of Peterborough.

THE Theobald Smith Gold Medal of the American Academy of Tropical Medicine has been awarded to Dr. C. M. Wenyon, formerly director of the Wellcome Foundation Research Laboratories. The Medal will be presented to Dr. Wenyon in London through the United States Embassy.

THE Veterinary Educational Trust has made the following awards: *Boots Undergraduate Scholarships* (£150 per annum): M. H. Cross (University of Liverpool), G. Shattock (Royal Veterinary College), G. Sumner Smith (University of Liverpool), H. S. Taylor (University of Liverpool). *Halford Undergraduate Scholarships* (£100 per annum): Gordon Cox (Royal Veterinary College), D. C. Croft (University of Liverpool). All the scholarships are awarded for the full course of study for the diploma of M.R.C.V.S. These awards bring the total of undergraduate scholarships so far awarded by the Trust up to eighteen. In addition, eight research fellowships of an annual value of £450–£800 have been awarded for the investigation of veterinary problems of urgent importance.

THE following appointments have been made in the University of Sheffield: Mr. L. Mirsky to be assistant lecturer in mathematics; Dr. J. A. Pope to be lecturer in mechanical engineering.

The following resignations have taken place: Dr. E. T. Goodwin, lecturer in mathematics; Mr. J. H. Read, lecturer in chemistry; Dr. J. Shirley, lecturer in geology; Dr. W. Davies, temporary assistant lecturer in geology; Colonel R. G. Bellamy, lecturer in mechanical engineering; Miss M. C. Simpson, assistant bacteriologist.

THE Genetical Society is holding special meetings during October 31–November 2, at which several European geneticists will describe work and thought in that field in their own countries, and British geneticists will speak on progress in Britain. The meetings will be held at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1.

THE Society of Czechoslovakian Mathematicians and Physicists is arranging a conference on the use of X-ray methods in the metal industry to be held in Prague during November 21–25. Some twenty-five Czech specialists and also invited guests from foreign countries will deliver lectures on the application of X-rays to the study of foundry sands, electrolytically deposited metals, deformation in polycrystalline materials, light alloys, fatigue in metals, welding, etc.; and on the use of gamma rays on material testing. The lectures will be published as a booklet. More detailed information about the conference can be obtained from Dr. V. Vand, 16 Woodburn Boulevard, Bebington, Cheshire, or directly from the Society of Czechoslovakian Mathematicians and Physicists, Prague II, Žitná 25, Czechoslovakia.

THE Council of the Polish Medical Association in the British Empire is appealing for books, text-books and periodicals which are urgently needed in Poland. During the German occupation, not only were no new books published but also the existing libraries were robbed and the most valuable books confiscated. The final stages of the War practically completed the destruction. Great efforts are now being made to train young people for the work of reconstruction. The greatest difficulty encountered in this task is the lack of books and text-books. The Association is particularly interested in books on medicine, and would be glad to receive such books, in English, German or French; volumes of the *Lancet*, *Medical Officer*, *Nature*, etc., would provide university libraries with material indispensable for the work both of students and staff. Correspondence should be sent to the president, Dr. B. Jedlewski, 43 Eaton Place, London, S.W.1.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Can the Iron in Peroxidase be Replaced by Manganese?

IN 1940[1] we demonstrated that pure horse radish peroxidase can be split reversibly into protohæmin and a colourless protein component. The original activity could be restored by mixing protohæmin and the protein. Later[2], we tested different iron-porphyrins for their ability to replace protohæmin. Only deuterohæmin and mesohæmin gave activity, both lower than protohæmin. Hæmatohæmin and many others were inactive. A graph, already published[2], shows that after one mol of hæmin per mol of protein is added, further addition of hæmin does not change the activity.

Gjessing and Sumner[3] cleaved impure peroxidase preparations according to our method, and investigated the activity resulting from addition to the protein part of (1) Cu-, Co-, Mn- and Ni-protoporphyrins; and (2) Fe-meso- and Fe-hematoporphyrin.

Copper, cobalt and nickel gave no activity. Some activity (28·4 per cent) was observed in one single test with the manganese protoporphyrin, whereas remarkably enough higher and lower additions gave practically no activity. Contrary to our experience, Gjessing and Sumner's protein preparations always gave strongly decreasing activity when the hæmins were added in increasing excess. We therefore considered it of interest to see if their positive result with Mn-protoporphyrin could be confirmed. The question is important, because iron is the only metal hitherto found in peroxidases, catalases and cytochromes.

We further know from our own experience that a positive peroxidase reaction in one single test is far from conclusive, since it may sometimes be caused by unknown impurities.

We prepared Mn-protoporphyrin by heating protoporphyrin in pyridine + acetic acid + chloroform with manganese acetate. It seems never to have been crystallized (we did not succeed in crystallizing it), so it was precipitated with water or ether, washed with water and dried. Mn found = 8·2 per cent, calc. 8·9 per cent. Absorption bands in pyridine: 593 and 572–542 mμ.

Pure horse radish peroxidase was split with acetone-hydrochloric acid in ice. The protein component contained 1·8 per cent of the original activity, that was restored to 80 per cent by the addition of 100 or 200 per cent of the quantity of iron-hæmin split off. Addition of 25, 50, 100, 200 or 400 per cent manganese hæmin gave no increase over the blank value tested both one and twenty-four hours after the addition. We thus feel justified in stating that manganese-hæmin is entirely incapable of giving any activity with peroxidase protein, though a spectroscopic change showed that a reaction, probably a coupling, occurred between Mn-protoporphyrin and protein. The light absorption, measured in a Zeiss photometer, increased during the reaction in the blue (*S* 47) and yellow (*S* 57) regions.

It should finally be pointed out that contrary to our experience Gjessing and Sumner found Fe-hæmatoporphyrin to be active (max. 76 per cent) and Fe-mesoporphyrin to be even more active than Fe-protoporphyrin. The discrepancy is probably due to the fact that Gjessing and Sumner worked with impure preparations.

HUGO THEORELL.

Vitamin C Peroxidasic Activity

ENZYMATIC oxidation of vitamin C, first recorded in 1921[1] and made more specific since 1928 by Szent-Györgyi, has given rise to the hypothesis that the vitamin acts as a constituent of dehydrogenating enzymes. However, so far as we know, direct evidence of the enzymatic activity of ascorbic acid has not been given. Our results show that vitamin C, acting as a peroxidase or as an antioxidant, can increase or reduce the already known peroxidasic action of ionized copper[2] and iron[3]. The experiments now reported consist in a comparison between the extinction coefficients of solutions, *A*, that contain an oxidizable substrate, ascorbic acid, hydrogen peroxide, copper sulphate and ferric chloride dissolved in 10 c.c. water, and solutions, *T*, devoided of vitamin, but similar to *A* in every other respect.

The freshly prepared ferric chloride solution contains 9 mgm. citric acid to each 10 mgm. iron. The measurements of the extinction coefficients were carried out in the Pulfrich Stuffenphotometer, 10 minutes after the starting of the reaction, and refer to a layer of 20 mm. The extinction coefficients in the spectral region of wave-length 470 mμ of the solutions *A* and *T* will be designed respectively by E_A^{470} and E_T^{470}, and the difference $\left(E_A^{470} - E_T^{470}\right)$ and the ratio E_A^{470}/E_T^{470} by E_{AA}^{470} and V. E_{AA}^{470} is positive or negative and V greater or less than 1 according as the vitamin promotes or checks the oxidation; the molar (atomic for Cu and Fe) concentrations are expressed in 10^{-4} gm. per litre.

Action of the vitamin on phenol. Standard solution: phenol 2 mgm. (21 m.); ascorbic acid, 1 mgm. (6 m.); hydrogen peroxide, 3·1 mgm. (91 m.); Cu, 0·48 mgm. (8 a.); Fe, 0·01 mgm. (0·2 a.). (See Table 1.)

Solutions *A* are brown-yellow, except for solutions 2 and 5 which take a pink tint turning to brown. Solutions *T* are colourless or yellow.

Cresol (1) *and tyrosin* (2). Standard solution: (1) phenol is substituted by 2·29 mgm. (21 m.) cresol; (2) tyrosin 2 mgm. (11 m.); ascorbic acid 2 mgm. (11 m.); hydrogen peroxide 6·2 mgm. (182 m.) Cu 0·48 mgm. (8 a.); Fe 0·02 mgm. (0·4 a.). (See Table 2.)

Solutions *A* of *ortho-*, *para-* and *meta*-cresol take respectively a brown-orange, brown-yellow and pink coloration. Solutions *T* are colourless or pale yellow.

Benzidin: Standard solution: benzidin 2 mgm. (11 m.); ascorbic acid 1 mgm. (6 m.); hydrogen peroxide 3·1 mgm. (91 m.); Cu 0·48 mgm. (8 a.); Fe 0·01 mgm. (0·2 a.); acetic acid 10 mgm. per 1 mgm. of benzidin. (See Table 3.)

Solutions *A* develop immediately a brown reddish coloration. Solutions *T* first give a faint blue tint turning to reddish-brown.

According to colorimetric measurements of the red tinted chloroform extracts of solutions A_1 and T_1,

with 2 mgm. of benzidin, 0·35 mgm. in the solution *A* nd 0·09 mgm. in the solution *T* are converted at he tenth minute of the reaction into the benzidin i-equivalent oxidized product, the diphenoquinone is-acetate-imide, $C_{12}H_{10}N_2(COOH-CH_3)_2$.

3–4 *Dioxyphenylalanin, called 'Dopa'* (1), *and yrogallol* (2). Standard solutions: Dopa 2 mgm. 10 m.); ascorbic acid 1 mgm. (6 m.); hydrogen eroxide 1·55 mgm. (46 m.); Cu 0·24 mgm. (4 a.); Fe = 0. (2) Pyrogallol 2 mgm. (16 m.); ascorbic cid 1 mgm. (6 m.); hydrogen peroxide 0·31 mgm. 9 m.); Cu 0·192 mgm. (3 a.); Fe = 0. (See Table 4.)

The Dopa *A* solutions take a brown coloration. olutions *T* develop a faint blue tint turning to the rown. Solutions *A* and *T* of pyrogallol give a brown nd pale yellow coloration.

The results of this investigation may be summarized s follows. Vitamin C and ionized copper and iron onstitute a monophenol peroxidase, while the vita- in and copper give a polyphenol peroxidase. The bserved activity of vitamin C seems, however, not o be exclusively limited to the transport of hydrogen, ut may also involve a deep modification of the henol molecule as suggested by the appearance of pink coloration in phenol solutions.

Hæmoglobin in Blood-sucking Parasites

THE hæmoglobins of different animals are not identical; the differences between them could be used as specific characters within a genus. In *Daphnia*, for example, the axes of the α-bands of oxyhæmoglobin, measured with the Hartridge reversion spectroscope, are at 5761, 5764 and 5766 A. in *D. obtusa* Kurz, *D. pulex* (De Geer) and *D. magna* Straus respectively, while for the larvæ of two species of the chironomid genus *Anatopynia*, the wave-lengths are 5769 for *A. varia* (Fabr.) and 5776 for *A. nebulosa* (Mg.). Moreover, hæmoglobins are not only specific: they also may be individual[1]. It is to be expected then that the hæmoglobins of a host and of its bloodsucking parasite will not be identical; yet this seems never to have been established. The only invertebrate parasites which suck the blood of vertebrate animals and have hæmoglobin in their own blood are certain leeches and copepods, and it has been supposed by some that the hæmoglobin of a parasitic copepod originates from that of its host, a fish, by passing through the gut wall of the parasite and accumulating in the blood of the latter[2].

There are two types of parasitic copepod with red blood, represented by *Lernanthropus* and *Lernæocera* (*Lernæa*). Van Beneden[3] in 1880 showed with the spectroscope that the blood pigment of the former is hæmoglobin; but the pigment of the latter has not hitherto been identified. Through the kindness of Miss N. Sproston and Mr. C. F. Hickling I have been able to examine the blood of *Lernæocera branchialis* (L.) from the gills of the greater forkbeard, *Urophycis blennoides* (Brünnich). The parasite's blood contains hæmoglobin, and the axis of the oxyhæmoglobin α-band is at 5790 A. (Hartridge spectroscope). That of the host's oxyhæmoglobin is at 5765 A. The two hæmoglobins are thus not only different, but also very different from one another. Among thirty-one species of animals examined, the wave-length of the oxyhæmoglobin α-band was found to be longest in *Lernæocera branchialis* and shortest in *Isidorella gibbosa* (Gould), a freshwater pulmonate snail from New South Wales. The α-band in this mollusc is at 5751 A., while in man it is at 5775 A.

It would be interesting to know the value, if any, of hæmoglobin to copepods, and whether there is a functional reason for its presence in some copepod parasites of fish and absence in others. Experimental work may solve the problem, but meanwhile it is not justifiable to assume[2] that in *Lernæocera* oxygen for respiration reaches the parasite through its mouth with the host's hæmoglobin, and that direct gas exchange between copepod and sea water is reduced to a minimum because the cuticle is relatively thick. Such a source of oxygen from the host is improbable, particularly when, as pointed out by the authors quoted, the parasite's meals are taken at rare intervals.

Œdema in Hamsters Infected with *Leishmania*

IN the course of work upon the chemotherapy of experimental kala-azar, I have observed that Syrian hamsters (*Cricetus auratus*) with long-standing infections of an Indian strain of *Leishmania donovani* sometimes develop severe œdema. Ascites and distension of the mesentery with fluid are the first signs of the condition. Later, gross œdema of the subcutaneous tissue develops and the skin is pulled down into a skirt around the flanks by the weight of the fluid it contains. The animal increases rapidly in weight through water retention and dies in a few days. An adult hamster weighing 80–100 gm. may gain 50 gm. in weight in the course of a week.

When this observation was first made in 1942, private correspondence with the late Dr. G. W. Dunkin of the Agricultural Research Council, who supplied the hamsters, confirmed the fact that the condition had not been recognized in stock animals.

The condition appears only after several months of infection with leishmania, and not every animal is affected. It does not depend upon the degree of infection as measured by parasite counts in spleen smears[1]. Œdematous animals are not suitable for use in tests for leishmanicidal substances, and the difficulty has been overcome by the use of recently isolated Mediterranean strains of leishmania, which produce heavy spleen infections in the course of a few weeks[2]. However, if animals infected with these strains are kept untreated for several months, some of them develop œdema. This shows that the condition is not associated with a single strain of leishmania.

Œdematous animals exhibit proteinuria; the kidneys are pale and enlarged, and histological examination shows degeneration of the glomeruli and obstruction of the tubules with protein casts. The serum protein in a few animals was determined by Walther's method[3]; the results for five œdematous animals were: 3·8, 5·4, 4·6, 3·5, 4·9 per cent of protein respectively, and for two normal animals of the same age, 7·1 and 7·6 per cent. It is evident that severe loss of protein through the kidney is the chief cause of the œdema.

All attempts to cultivate a secondary infective agent upon nutrient media or by inoculation of normal animals have so far failed. Intraperitone and intracerebral inoculations into mice and hamster, and inoculation of chick tissue-cultures with a candle suspension of kidney, liver or spleen material fro œdematous hamsters have also been without resul It seems probable that the nephritis is caused by toxin liberated by the leishmania parasite und conditions of chronic infection.

The condition of the hamsters recalls that observe in mice infected with *Trypanosoma cruzi*, which h been investigated by Collier, Fulton and Innes[4]. Th underlying cause of the œdema is not, however, th same, because these workers found the kidneys œdematous mice to be normal.

Production of *p*-Aminobenzoic Acid b the Tubercle Bacillus

MANY workers have claimed that the commo sulphanilamides in high concentrations may modif the course of experimental tuberculosis in animal Much better results have been obtained, however with the diaminodiphenyl-sulphone and some of it derivatives, for example, promin and diasone. Th same applies to promizole, an analogous compound which is a diaminophenyl-thiazole-sulphone. Thes sulphones have also shown a certain effect in a prolonged clinical trial, although it is necessary to see for more effective, or at least less toxic, compounds

The diaminodiphenyl-sulphone and similar compounds are said to act on sensitive bacteria in th same manner as the sulphanilamides. The fundamental condition for the effectiveness of these compounds against the tubercle bacillus would therefor appear to be that this bacterium also requires *p*-aminobenzoic acid as an essential metabolite. Indirec proof of this is furnished by the observation that th bacteriostatic action *in vitro* of sulphathiazole[1] an promin[2] on the tubercle bacillus is inhibited b *p*-aminobenzoic acid. We have, however, performe direct analyses[3], and succeeded in showing that bot the tubercle bacillus and the culture medium i which it has been grown contain *p*-aminobenzoic acid Assuming that *p*-aminobenzoic acid is of function significance to the bacterium which forms it—an this is highly probable—the experiments with sulph ones and related substances in experimental tuberculosis can therefore be considered as well founde

The determinations were performed in the followin manner. A number of flasks, each containing 200 m of Sauton's synthetic substrate, were inoculated wit a virulent human strain (a platinum loop containin on the average 0·1 gm. of wet bacilli). The culture were incubated at 37° C. for different times. Th resultant cakes of bacteria were finely dispersed an washed and dried by suction. The filtrate wa sterilized by heat (passage through a Seitz filter di not alter the values) and continuously extracted wit ether at *p*H 3·8 for 30 hours. *p*-Aminobenzoic aci was determined colorimetrically in the ether solutio

Time of cultivation (days)	Amount of p-aminobenzoic acid formed in substrate. (μgm. per flask of 200 ml.)			Amount of moist bacteria formed. (gm. per flask of 200 ml.)	Amount of p-aminobenzoic acid formed in bacteria. (μgm. per gm. moist bacteria)		
	Without hydrolysis	After alkaline hydrolysis†	Total		Without hydrolysis	After alkaline hydrolysis†	Total

10	2·5	1·1	3·6	1·3	—	—	—*
30	6·5	2·0	8·5	3·9	0·3	0·6	0·9

* Quantity of bacteria too small for exact analysis.
† A more intense hydrolysis may perhaps give higher values.

with p-dimethylaminobenzaldehyde[4]. The residue from the ether-extraction was made normal with respect to sodium hydroxide and autoclaved for 30 minutes at 15 lb. pressure for the liberation of the bound form of p-aminobenzoic acid[5]. Alkaline hydrolysis is more effective here than acid hydrolysis. The hydrolysate was extracted with ether in the manner described above.

The washed bacteria were autoclaved with ten parts of water at the same pressure and for the same ime as above. The free p-aminobenzoic acid was determined in the filtrate. The remaining bacteria were treated in the same way with ten parts of normal sodium hydroxide in order to liberate the conjugate form of p-aminobenzoic acid.

All reagents and the constituents of the culture medium were free from p-aminobenzoic acid. The method may be regarded as rather specific; of the substances which might be thought to give a disturbng effect, tryptophan produces another colour and kynurenin is not extractable at pH 3·8[6].

The values obtained are given in the table, from which it follows that p-aminobenzoic acid is formed and excreted by the tubercle bacillus. It is an interesting point that larger quantities are found in the substrate than in the bacteria themselves. It would also seem that the proportion of p-aminobenzoic acid in the free form is higher in the substrate than in he bacteria.

Theory of the Formation of Hydrochloric Acid in the Gastric Mucosa

IN a previous communication[1], the formation of a igh degree of acidity (pH 1·7–1·8) during fermentaion by ordinary bakers' yeast was described. Acid ormed to this extent in the suspending fluid (0·6 part o 1·0 of yeast) when unbuffered and containing potassium chloride of about 0·1 M strength or more. The mechanism of the formation consisted in an organic acid—such as pyruvic or phospho-pyruvic cid—exchanging its hydrogen ions for the external otassium ions. In this way an external hydrochloric cid content of about $N/50$ was developed. A similar mechanism for gastric hydrochloric acid was indicated, and throughout 1943–44 many experiments were carried out on human subjects after test meals, blood and gastric contents being analysed. Experiments were also carried out on rats and rabbits, the results being presented by one of us in a thesis on "Studies in the Relation of Keto-Acids to the Secretion of HCl by the Gastric Mucosa"[2].

Meanwhile, a more extended study of the occurrence in yeast appears to indicate that the acidic system involved is not mainly the pyruvic, but includes at least some other acid closely related thereto in the metabolic chain.

Owing to the publication this year of a paper by Bull and Gray[3] outlining a theory of hydrochloric acid excretion by the stomach, in some respects similar to that worked on since 1943 by us, attention is here directed to the latter and the work done in relation thereto. In our view the essential process consists in the secretion first of potassium chloride solution of about isotonic strength into a membrane lined tubule (which may be identified with the canaliculus in the parietal cells). As it passes along the tubule an exchange of hydrogen and potassium ions occurs, just as occurs in fermenting yeast with potassium chloride outside. The necessary organic acid is assumed to be formed in localized cell regions impinging on the canaliculus. No assumptions need be made throughout of a permeability other than that holding (say) for the muscle fibre membrane[4] or the yeast cell. With this view the movement of hydrogen ions across the membrane is apparently more effective than back into the cell; but again this also appears true for the yeast transfers, though another explanation may be more correct than a difference in velocity of passage. As the potassium ions pass back into the cell, the organic acid anions are continuously removed by oxidation, leaving bicarbonate ions in association with potassium ions and much free carbon dioxide. We may suppose K and HCO_3 ions passing across the boundary of the cell, because there the product of their concentrations is greater than outside; but as K and Cl are being extruded into the canaliculus, we may regard the events for the K ions as a circulation in the cell, with HCO_3 exchanging for Cl ions across the cell boundary.

A point of much importance arises in connexion with the formation of carbon dioxide by decarboxylation. It is generally taken for granted that the free gas is directly formed, but for yeast carboxylase at least, this can be shown to be incorrect[5], carbonic acid being first produced. As the process of decarboxylation is very likely similar for the animal cell, we may suppose carbonic acid also formed from keto-acids. Where there is an exceptional degree of activity associated with keto-acid breakdown, the presence of carbonic anhydrase would appear to be useful in hastening the change to carbon dioxide as the $KHCO_3$ diffuses back. This theory has the advantage over others in that there is a readily producible biological model forming free hydrochloric acid in an essentially similar way, and no other permeabilities need be assumed than those observed for the muscle membrane[4].

Seeing that free carbonic acid is produced in decarboxylation, the idea may be entertained that, after all, it is this acid which provides the free hydrogen ions. Our present reasons for supposing that this is not the main source (and it may be certainly held to provide some fraction) is that the true first ionization constant of carbonic acid given as around $10^{-3.5}$ does not appear sufficiently high unless strong concentrations of the acid are localized. Secondly, even *in vacuo* the high formation of acid in the external fluid proceeds with fermenting yeast, and the total carbon dioxide is reduced to a low figure. More experimental work is, however, required in this connexion.

The theory will be discussed more fully elsewhere.

A Neutral Solvent for Melanin

Melanin from the ink sac of *Sepia officinalis*, from a melanoma, and that prepared by the action of tyrosinase on tyrosine has been found to be soluble *in the cold* in ethylene chlorhydrin, $CH_2Cl.CH_2OH$.

Previously melanin had been thought to be soluble in diethylamine, but further investigation showed that in fact the solvent had combined with water vapour to form an alkyl hydroxide, and the resulting solution was strongly alkaline. It was also thought that 1 : 2-dihydroxypropane was a solvent, but on evaporation it was found that the resulting blackish-brown substance no longer had the properties of melanin. In the case of ethylene chlorhydrin the solution is neutral, and the substance remaining after evaporation is indistinguishable from the original melanin. The solubility increases with heat, and no change has been detected in the recovered melanin after treatment with the solvent in a Soxhlet extractor.

No guarantee of the purity of the melanin being possible, no attempt has been made to determine the precise degree of solubility, but it is very evident that both tumor and *Sepia* melanins are much more soluble than that obtained from tyrosine. No conclusions can be drawn from this fact, as it is not possible to state whether the tumor and *Sepia* melanins are or are not combined with a protein.

The work has been carried out with the aid of a grant from the Government Grant Committee of the Royal Society.

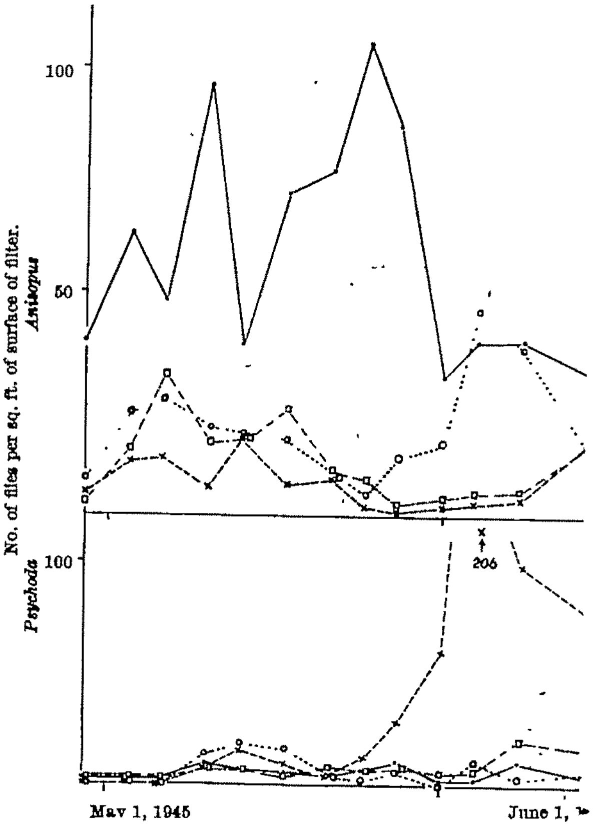
Control by D.D.T. of Flies Breeding in Percolating Sewage Filters

Nuisance often arises from the emergence of large numbers of flies from percolating filters treating sewage, situated near dwelling-houses or busy thoroughfares. Species which have caused most trouble are *Anisopus fenestralis*, *Psychoda alternata* and *Psychoda severini*. Various methods of control have been tried, including treating filters with creosote or bleaching powder, and flooding the filters with sewage; flooding can only be used, however, where the construction of the filter is suitable. The toxic substances so far used are non-selective in thei action; the concentrations necessary to kill fly larvæ also kill other members of the valuable population of scouring organisms, such as Collembola and enchytræid worms, as well as bacteria and fungi which form the active biological film on which th purifying efficiency of the filter depends.



Nos. of *Anisopus* and *Psychoda* trapped on percolatin sewage filters treated with creosote, bleaching powde and D.D.T.

		Date of treatment
• ——— •	Control	
× - - - - ×	Creosote	April 24
o ········ o	Bleaching powder	April 16
□—·—·□	D.D.T.	April 26

Experiments on the treatment of small experiment filters with D.D.T. in the form of (*a*) a powder applie at a rate of 300 lb. of D.D.T. per acre, and (*b*) a emulsion of D.D.T. in naphtha or kerosene at a ra of application of 50–100 lb. of D.D.T. per acre, showe that more than 90 per cent of the larvæ of *Anisopu* and *Psychoda* were killed, but that the Collembo and enchytræid worms were unaffected. Prelimina tests show that D.D.T. in these concentrations is no toxic to the bacteria and fungi in a filter, and th has no deleterious effect on its purifying capacity. The accompanying graph shows the results of an experiment on a large scale at the Minworth Works of the Birmingham Tame and Rea District Drainage Board. During the period April 16–26, 1945, filters were treated with the following substances: creosote 400 gallons per acre), bleaching powder ($6\frac{1}{2}$ tons per acre), and D.D.T. in the form of emulsion (75 lb. D.D.T. per acre); the numbers of emergent *Psychoda* and *Anisopus* flies caught in standard traps on the surface of the filters were then observed. Treatment with creosote gave the greatest reduction in numbers of *Anisopus*, but all the scouring organisms in the filter were killed and the biological film which later accumulated supported a secondary population of *Psychoda*. Bleaching powder caused the biological ilm to be discharged from the filter, and later there was a secondary peak in the emergence of *Anisopus*. With D.D.T. the numbers of both flies were greatly educed and an active population of worms (*Pachytrilus lineatus*) and Collembola (*Achorutes viaticus*) remained and kept the growth of biological film in check.

Further experiments are being made, particularly to ascertain the minimum quantities of D.D.T. and the best method of application to control filter flies. At present D.D.T. is not available for civilian use; the possibility of applying it for control of flies at sewage works would, of course, depend on its price in comparison with the cost of alternative poisons.

Use of Hydrochloric Acid for Softening Algal Tissues for Microtome Sections

In view of the increasing interest in marine algæ it seems apposite to record a method of treatment which has been found useful in preparing microtome ections of some Florideæ with particularly firm thalli. Formalin-alcohol, although a good fixative or cytological purposes, tends to harden such thalli, making them difficult to cut by microtome. Moreover, in those species which have an abundance of mucilaginous substances between the cells, the sections, when floated on water, swell considerably, twist, and escape from their casing of paraffin-wax. These difficulties can be avoided by treatment with warm ydrochloric acid in the case of *Chondrus crispus*, *Gigartina mamillosa*, *Gracilaria confervoides* and *Rhodymenia palmata*.

The method of treatment has been to put a covered dish containing a mixture of 90 c.c. of 70 per cent alcohol and 10 c.c. of hydrochloric acid in the embedding oven. When the liquid has reached the temperature of the oven, the piece of thallus to be eated is transferred to it from 70 per cent alcohol. he duration of the treatment required by different materials can only be found by experiment as it aries not only from species to species, but from the ounger portions of the thallus to the older. For example, young pieces of *Gigartina mamillosa*, after fixation in formalin-alcohol, require 15 minutes, hereas similar pieces of *Chondrus crispus* require nly 5 minutes. The duration of treatment should e kept to the minimum as continued immersion interferes with the staining of the nuclei and ultimately causes disintegration of the thallus. After treatment the thallus is washed thoroughly in 70 per cent alcohol and embedded in the usual way.

Of the algæ mentioned above, *Gracilaria confervoides* cuts reasonably well untreated, but sections of treated material are definitely superior. *Gigartina mamillosa* is very difficult to cut untreated after fixation in formalin-alcohol, but the youngest portions of the frond can be cut without treatment after fixation in Karpechenko's fluid. Even so, better results can be obtained by the use of hydrochloric acid. This is indispensable for the older parts of the frond, fixed in Karpechenko's fluid, but the time required is shorter than after formalin-alcohol. The improvement in all cases is more marked with sections cut at 5 µ than at 10 µ.

Activation Energy of Ionic Migration in Molten Salts

The conductivity of ionic melts, such as alkali and alkaline earth halides, can be represented fairly well by an equation $\varkappa = Ae^{-C/RT}$, where C may be regarded as the energy necessary to effect the configurational change occurring in ionic migration. Deviations from this equation, C varying with temperature, are found with some salts of a partially covalent character, for example, zinc chloride and lead chloride; with these salts, constitutional changes, such as dissociation, are likely to occur on rise of temperature.

The viscosity of ionic melts can be represented approximately by a similar equation: $\eta = A'e^{B/RT}$, where B is the energy necessary to produce the configurational change in viscous flow. Here also deviations have been recorded with some compounds of a partially covalent character[1]. Tabulated values for B[2] and C[3] are shown below.

	Equiv. conduct. (temp. 10 per cent above melting point [abs.])	C in cal./mole	B in cal./mole	r_A/r_C
LiCl	181	1150	8800	3·01
NaCl	149	1540	9400	1·91
KCl	120	2300	7800	1·36
RbCl	95	2830	—	1·22
CsCl	82	3330	—	1 07
NaBr	145	1840	10600	2·05
KBr	105	2550	7960	1·47
NaI	150	1250	7400	2·27
KI	106	2750	9200	1·62
$CaCl_2$	65	4100	9500	—
$BaCl_2$	78	4150	—	—

The activation energy of viscous flow (B) is always greater than that of ionic migration (C). This must be due to a difference in mechanism between the two processes. Viscous flow is determined to a greater extent by the large anions than by the small cations. On the other hand, the electric conductance of the alkali halides is mainly due to the small cations, while the contribution of the large anions is very much smaller[4]. This is shown by the fact that the equivalent conductivity changes strongly with change of cation but very little with change of anion. These salts are predominantly cation-conductors in the solid state also[5].

Thus, viscous flow involves a more far-reaching configurational change and higher energy barriers than ionic migration. It is therefore not surprising that there is no simple relation between conductivity and viscosity of molten salts. For example, the temperature coefficients of the two properties are not equal.

With the alkali chlorides there is a distinct increase of the activation energy (C) from lithium to cæsium, together with a decrease of the ratio of anion to cation radius (r_A/r_C). The small values for lithium chloride and sodium iodide are probably due to comparatively small energy barriers in systems in which r_A/r_C is great; in the case of lithium chloride, the small cations must have considerable freedom of movement between the large anions in contact.

The C-values of the alkaline earth chlorides are greater than those of the alkali chlorides because of the stronger electric field in an assembly containing bivalent ions, and also because these molten electrolytes—by analogy with the solids[5]—may be expected to be anion conductors.

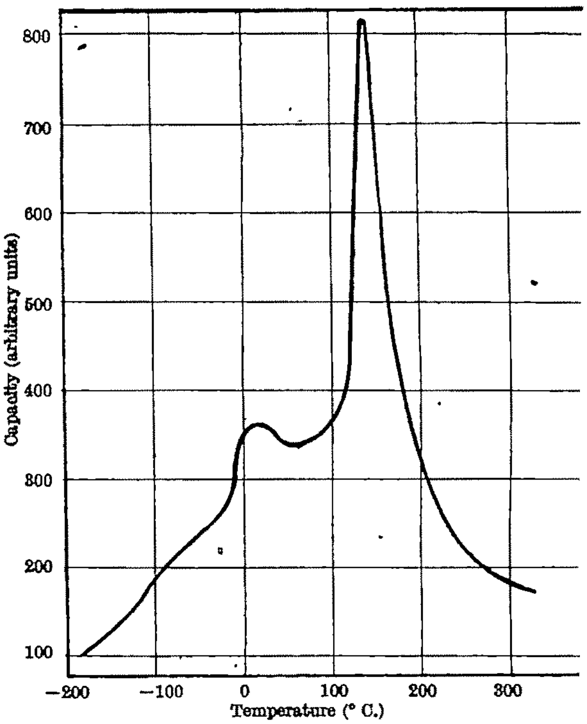
Dielectric Constants of Some Titanates

THE oxides and carbonates of beryllium, magnesium, cerium, zinc, strontium, cadmium and barium were heated with titanium oxide to a temperature of about 1,500° C. The dielectric constants of the titanates thus obtained were, for beryllium titanate 70, for magnesium 17, for calcium 115, for zinc 30, for strontium 155, for cadmium 62, exceeding 1,000 for barium. The measurements were carried out at room temperature at a frequency of 1 M Hz.

The titanates may be divided into two groups according to their place in the periodic system and the values of their dielectric constants. The titanates of beryllium, calcium, strontium and barium belong to the first group, and those of magnesium, zinc and cadmium to the second one. Such a division in general coincides with the division of the titanates according to the type of their crystal lattice. The crystal lattices of the titanates of calcium, strontium and barium are of the perovskite type, whereas those of magnesium and cadmium are of the ilmenite type. The atomic or ionic polarizability depends upon the structure of the crystal, and for this reason the magnitude of the dielectric constant depends upon the type of the lattice.

The dielectric constants of the perovskites investigated were found to grow with the increase of the size of the alkaline-earth ion. The electron polarizability of the ion increases with the radius. A more important factor, however, is that with the increase of the radius of the alkaline-earth ion located in the centre of the elementary cell, the distance between the titanium and oxygen ions increases as well.

Barium titanate having a very large dielectric constant, the distance between the titanium and the oxygen ions exceeds the sum of their radii. Such a 'loose' structure of the crystal lattice leads to considerable atomic polarizability.



The dielectric constant of barium titanate varies considerably with the temperature. The variation of the capacity of a barium titanate condenser with the temperature is shown in the accompanying graph.

The present investigation was carried out with J. M. Golgman. A more detailed article will be published in the *C.R. Acad. Sci. URSS*.

A Photographic Method of Deriving Isoclinics in Photo-elastic Methods

IT is well known that the chief cause of inaccurac in the photo-elastic method of stress analysis lies i deriving the isoclinics. We have used a photographi method which has greatly improved the accurac with which the isoclinics can be drawn. It consist of varying the load on the model so as to blur ou the isochromatic pattern (mercury green), leaving th isoclinics superimposed on a uniform grey background. The intensity of the light source is so adjuste as to enable a 30-sec. exposure of the photographi plate to be given, and the load is varied between quarter and three-quarters of the full load used t take the isochromatic pattern. The reduction t three-quarters of full load is advisable to prever fatigue failure. The model is carried through thr complete cycles during the exposure.

SOCIETY FOR APPLIED BACTERIOLOGY

AT the annual summer conference of the Society of Agricultural Bacteriologists, which was held at the Midland Agricultural College during July 23–25, plans were approved for a change in the title and range of interests of the Society. It has now been renamed the Society for Applied Bacteriology.

For some years the Society has, in fact, ceased to confine its interests entirely to the agricultural field and has attracted to its membership bacteriologists working in such fields as water supplies, sewage disposal, fisheries, food manufacture and various industries, as well as those in academic institutions whose work brings them into contact with the applied aspects of the subject. The inauguration recently of the Society for General Microbiology has fortunately provided a common meeting-ground for the discussion, by microbiologists working in all fields, of the more fundamental aspects of the science. There is, however, a large number of bacteriologists for whom hitherto no adequate society has existed, and whose needs are only partially satisfied by discussions at the 'fundamental' level. At a time when scientific men are being called upon more than ever to contribute to improvements and new processes in various industries, it is essential that those working in applied bacteriology should have facilities for meeting and discussing matters of mutual interest.

Membership of the Society for Applied Bacteriology is open to all who are interested in bacteriological problems. It is intended to hold an annual conference in the summer at different centres in the British Isles, and a shorter meeting in London in the winter. For the time being, papers, or abstracts of papers, will be published in the *Proceedings* of the Society. It is hoped that eventually the Society's publication will increase to the size of a journal. The officers of the Society are: *President:* Dr. L. A. Allen, Water Pollution Research Laboratory, Watford; *Secretary:* Mr. D. A. McKenzie, Provincial Laboratory, 36 Otley Road, Leeds; *Treasurer:* Mr. L. J. Meanwell, United Dairies (Wholesale), Ltd., Ellesmere; *Editor:* Mr. A. Rowlands, National Institute for Research in Dairying, Shinfield, Reading. The annual subscription is at present one guinea.

A survey of the papers at the summer conference follows.

A paper dealing with the teaching of bacteriology emphasized its unassailable claim to be taught as a science; its students are trained as bacteriologists in the widest sense, able to apply their knowledge and experience to any and every problem of a bacteriological nature, and not restricted to the relatively narrow field of its applications to some other science. With this ideal in view, a plea was made for the establishment at universities of independent departments of bacteriology, with the provision of a science degree, or at least a diploma, in bacteriology. A suitable curriculum was outlined together with observations on the teaching methods that should be applied, a distinction being drawn between the requirements of those intending to follow a career in bacteriology, and others for whom a knowledge of its applications in their own particular sphere was the only essential.

The origin and development of the National Collection of Type Cultures was described, together with an account of its organization and work. In view of the facilities now provided for the microbiologist by the type culture collections, their future is of considerable importance, and the problem was thoroughly discussed.

A contribution dealing with bacterial growth in aerated and quiescent flax infusion described the chemical changes produced. With quiescent cultures, the liquor obtained is acidic in nature, frequently containing appreciable amounts of volatile acids. Industrially, such a liquor tends to be evil-smelling, difficult to treat for purposes of disposal, and unsuitable for re-use in an industrial process. With aerated cultures, on the other hand, the reaction tends to become alkaline, with a much smaller and sometimes negligible content of volatile acids. Reduction of the organic carbon content, which as shown by the carbon balance sheet can be accounted for by the carbon dioxide produced by bacterial action, is reflected in a reduction of the polluting strength as shown by the usual methods of measurement.

A study of the microflora of immersion brines emphasized the many problems that require elucidating, not only as regards the curing process itself, but also as regards the bacteriological technique to be applied in studying the bacteria involved.

Water supplies used for dairy purposes at many Welsh farms and dairies were shown to be heavily polluted, and their purification by chlorination has been investigated. The residual bacterial flora of tap, well and clear river water was in all cases negligible following treatment for ½ hr. with 10 p.p.m. chlorine. A 2 hr.-contact period using 50 p.p.m. chlorine was necessary to attain similar results with turbid river water. False-positive presumptive coliform results obtained with chlorinated stream water were caused by an organism resembling *Bacillus polymyxa*.

Further evidence of the value of a modified Hotis test (plating Hotis-positive samples on crystal violet blood agar), not only in reducing the work involved, but also in increasing the number of positive samples, was adduced from the results of the examination of 639 quarter samples known to be, or suspected of being, infected with *Streptococcus agalactiae*.

Methods for the bacteriological examination of milk continue to receive much attention. In a discussion of the choice of a suitable yardstick for evaluating tests, it was pointed out that no single test at present available is adequate to cover the whole range of producer, distributor and consumer requirements. A further paper dealt with the effect of temperature variations in the region of 37·5° C. on the reduction of methylene blue and resazurin in milk. Results show that at temperatures between 31° C. and 43° C., the acceleration of reducing action and the gradual inhibition of bacterial growth in milk by increasing temperatures more or less cancel out, mean differences in reduction times being well inside the experimental error of about ½ hr.

With the introduction of the National Milk Testing and Advisory Scheme, bacteriological tests and standards for the examination of washed churns were prescribed. Towards the end of 1944, 5,400 churns at 1,110 milk depots in England and Wales were being tested monthly by these methods. Results obtained in Wales showed that mechanically washed churns were, in general, bacteriologically more satisfactory than those washed by hand and then steamed over a jet, although at dairies dealing with a small number of churns daily (less than fifty), which allows of adequate time for steaming both lids and churns, equally satisfactory results were obtained.

The effect of contamination from churns on the bacteriological and keeping quality of both raw and pasteurized milk was the subject of another paper. There is in general no measurable effect, unless the number of bacteria added by the churns is at least equal to that initially present in the milk. Churns which have been mechanically washed efficiently are without effect on the keeping quality of the milk, and no advantage accrues from further steam sterilization of such churns.

The *Proceedings* of the Society, containing full abstracts of the papers read at the conference, may be purchased from the honorary treasurer.

BRITISH ELECTRICAL ENGINEERS AND THE WAR

AT the opening meeting on October 4 of the current session of the Institution of Electrical Engineers, Dr. P. Dunsheath delivered his presidential address, in the course of which he gave a broad survey of some of the contributions made by British electrical engineers to the successful outcome of the greatest war in history. The scope of the address was very wide and covered such subjects as the maintenance of the electric power supply of Great Britain, the considerable increase in communications both at home and overseas, the use of broadcasting and radar as defensive and offensive weapons, the defeat of the magnetic mine, radio aids to navigation and gun-laying, the improvement of searchlights and the development of electrical equipment for research on atomic energy. The success attained in all this work was in no small measure due to the extensive and ready co-operation which was built up between the Services and the electrical industry for the purpose of solving the many problems of design and production which continually arose. In giving some general facts about the above contributions, Dr. Dunsheath disclosed some striking figures concerning the various phases of electrical engineering as adapted to war-time requirements.

The problem of the maintenance of an adequate electric power supply had to be tackled in the face of such difficulties as the destruction of, or severe damage to, certain generating stations by enemy bombing, and the interruption of service due to the breakdown of the overhead wires of the Grid system. The large majority (about 73 per cent) of the faults on this overhead distribution system were caused by trailing cables of barrage balloons which had broken loose; and only some 14 per cent were directly attributable to enemy action. For strategic reasons it became necessary early in the War to effect a major transfer of munition works to South Wales and the south-west of England; and the resulting change in load distribution imposed a very onerous task on the national control organization of the Central Electricity Board. Having in mind the additional difficulties of obtaining materials, suitable coal and adequate labour, there can be no question that the successful operation of a system of public supply stations with an output in 1944 of more than 38,000 million kWh., which was an increase of nearly one half on the 1939 output, is an outstanding performance.

As the supply of electric power for industrial purposes was a prime war-time necessity, so was the maintenance and extension of communications between different parts of the country and overseas In this field the British Post Office provided a vast private-circuit network for the operational, meteorological and administrative traffic of the Fighting and allied Services, and enlarged its peace-time trunk system to reduce delays in priority traffic concerned mainly with the supply of munitions. Much progress was made during the War in the equipment used on audio carrier current and coaxial cable systems with the object of making each circuit carry as many communication channels as possible. Where it was necessary or expedient, radio links operating on ultra short wave-lengths were installed and used as an integral part of the land-line network. In spite of various precautions taken before and during the War many disasters due to enemy action overtook the Post Office. For example, a single high-explosive bomb on the Old Bailey on May 10, 1941, severed 28 cables of different types and interrupted 5,200 working circuits, mainly long-distance.

Overseas communications for the Services, necessarily of a secret nature, were carried out mainly by the submarine cable system, a network of 155,000 nautical miles which suffered many vicissitudes during the War due to enemy action and other causes. The enormous quantities of Press traffic, etc., were mainly cleared on wireless circuits; and on the long-distance service an outstanding war-time technical development was the extension of relay working to avoid interruption of the service by unsuitable ionospheric conditions. Another remarkable development in British electrical engineering enterprise during the War was in connexion with the wireless transmission of photographs, drawings, etc. Although the whole of the London photo-telegraph apparatus was lost during the raids of May 1941, the number of circuits on which photographs can be transmitted has been increased from three to eleven, and some two thousand facsimiles are now being exchanged monthly over direct circuits between London and the principal cities of the world.

The British broadcasting service was outstanding during the whole of the War in providing entertainment, news and stimulating programme items so necessary in keeping public morale at a high level In addition, an important job, not perhaps adequately appreciated by British listeners, was carried out in providing listeners in the occupied countries of Europe with their only access to truth in news and their only means of contact with the world outside Nazi domination. As a result of the war-time effort of our electrical engineers, Great Britain now possesses the world's largest long-wave broadcasting station capable of delivering to the aerials a power of 800 kW. as well as the world's largest short-wave broadcasting station, at which there are twelve transmitters, each capable of delivering 100 kW. to one or other of th fifty-one directional beam aerials. In order to improve home reception and to provide for local broadcasting in the event of the interruption of communications due to invasion, the B.B.C. built sixty-four small broadcasting stations, which were synchronized and operated on one wave-length—an outstanding technical achievement. These were finally closed on July 28, 1945, when the Corporation changed over to the first instalment of peace-time broadcasting.

During his address, Dr. Dunsheath referred at som length to the development and applications of radar both as a defensive and as an offensive instrumen of war. This technique, developed first as a means of detecting attacking enemy aircraft, and later used as an entirely novel form of navigation and for the precision bombing of enemy targets on and, sea or in the air, is now well known as one of the outstanding achievements of the War, in which scientific workers, engineers, industry and the Services have co-operated with complete success. This work brought in its train remarkable developments in the technique and output of valves, cables with novel dielectrics, cathode ray tubes and many other components. The facts that a modern battleship carries about fifty transmitting sets of various kinds, and many more receiving sets, and that a Lancaster bomber fully equipped may require about four hundred valves, accounts for the statement that during the last year of the War thirty-eight million thermionic valves were produced for the Services as compared with a peace-time demand of a quarter of a million.

There are many other electrical engineering applications which have been exploited to the full during the War, such as the clearing of fields of magnetic mines and the fitting of ten thousand warships and merchant vessels with degaussing equipment, the improvement of searchlights and their automatic direction by radar control, and the lighting of ports, shipyards and other important open areas under conditions of severe restrictions.

Dr. Dunsheath was only able to make a passing reference to the importance of the corporate work of the Institution of Electrical Engineers, and to the teaching profession, in providing an adequate supply of trained and experienced personnel of all grades. Without the assistance of large numbers of trained personnel, many of the engineering and scientific achievements of the electrical engineer during the War would never have come to fruition.

SCIENTIFIC STUDY OF FELLMONGERING

THE wool trade and, later, the cloth trade are the two industries on which the wealth of medieval England was founded, and wool production is still one of the leading industries of the British Empire. Though large quantities of wool are taken from the living sheep at the annual shearing, a good deal comes from slaughtered sheep. The handling of the sheepskin after flaying, and the separation of the wool from the pelt, are the tasks of the fellmonger, who in many cases is carrying out his work to-day by the same methods as those employed by his ancestors hundreds of years ago. Fellmongering, however, like a number of other ancient crafts, has now become the subject of scientific research. Bulletin No. 184, recently issued by the Council for Scientific and Industrial Research of Australia (Melbourne: Gov. Printer, 1945), describes a series of important fundamental investigations on the fellmongering process carried out by F. G. Lennox, Margaret Maxwell and W. J. Ellis.

There are, speaking very roughly, two types of sheep farmed in Australia: the Merino sheep, with long fine wool and, even at best, a poor pelt, and the crossbred sheep with shorter, coarser wool and a better pelt. There are also two general methods of de-wooling. The older process, with origins lost in antiquity, is known as 'sweating'—the sheepskins are hung in a warm moist atmosphere until the wool loosens and can be pushed off the pelt by the hand, the wool fibre coming away complete with root. The more recent process is 'painting'; the skins are covered on the flesh side with a thick cream of lime and a reducing agent, generally sodium sulphide, and the alkali plus reducing agent travel through the skin and cause the wool fibre to break off just above the root. The painting process therefore leads to a slight shortening of the fibre, and the total loss of weight from this cause is sufficient to keep the older sweating process in being for Merino sheepskins, in spite of the considerable damage frequently done to the pelt, and the foul odour of the sweating chambers.

The present pamphlet contains twelve papers describing studies on wool-loosening by the sweating process, the effect on the pelt not being included. It is interesting that the foundation of the work is the development of a quantitative method for measuring the force required to detach a standard staple from the pelt. With this tool in the hands of the investigator, it becomes possible to study, with some accuracy, the effect of varying conditions on the rate at which the wool root is loosened from its base.

The active agents in the sweating process are bacteria; an ærobe, an atypical strain of *Proteus vulgaris* designated No. 7, being the dominant wool-loosening organism, though three or four other species also have the same effect. No. 7 exists sparsely at the wool roots at the start of the sweating process, and freely when the wool is ready to pull. The agents of putrefaction which damage the pelt are anærobes. Many skins from up-country kills are dried for transport and have to be soaked back by the fellmonger before they can be sweated. Studies of this soaking operation show that the soak-water is completely de-oxygenated, a condition which encourages the growth of putrefactive anærobes. This, however, does not appear to inhibit the growth of No. 7 in the sweating chambers, and oxygenating the soak-water does not accelerate wool-loosening.

During sweating a large amount of ammonia is produced. Ammonia itself has a wool-loosening action, but the accumulation of ammonia tends to inhibit bacterial wool-loosening. The action of ammonia is due to the NH_3 molecule. Aliphatic amines have a similar effect, though this diminishes with increasing size of the molecule, quaternary ammonium compounds having little activity. Lipid solvents similarly have a wool-loosening action, while reagents causing dehydration, such as acetone and solutions of sodium chloride, and even drying, have a wool-tightening action. Conditions which cause tissue-swelling also cause tightening, probably because the hair-bulb cannot pass up the follicle.

The impression left on the reader of the twelve papers is of work well planned, well executed and well reported. An interesting development of the research is a new method of de-woolling the numerous small scraps from the edges of skins treated by the painting process, as well as shanks and head pieces. In these the scraps of pelt have no commercial value, and it has been shown that by subjecting them to heat treatment at 65° C. the skin tissues can be completely hydrolysed by proteases prepared from a bran culture of *Aspergillus flavus-oryzæ* or by papain, leaving the wool undamaged.

The volume well illustrates how even the oldest craft can be improved by an understanding of its scientific basis, and further developments will be awaited with great interest.

D. JORDAN LLOYD.

FORTHCOMING EVENTS

Saturday, October 20

Royal Institute of Chemistry, London and South-Eastern Counties Branch (at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1), at 2.30 p.m.—Discussion on "The Publicity of Science, with particular reference to Chemistry" (Dr. O. J. R. Howarth, O.B.E., Mr. O. F. Brown, Mr. G. A. Jones and others).

Institution of Mechanical Engineers, Graduates' Section (at Storey's Gate, St. James's Park, London, S.W.1), at 3.30 p.m.—Mr. R. Gore: "A System of Production Control".

Tuesday, October 23

Royal Anthropological Institute (at 21 Bedford Square, London, W.C.1), at 5 p.m.—Prof. V. Gordon Childe: "The Science of Man in the U.S.S.R."

Zoological Society of London (at Regent's Park, London, N.W.8), at 5 p.m.—Scientific Papers

Institute of Physics, Electronics Group (in the Reid-Knox Hall, British Institute of Radiology, 32 Welbeck Street, London, W.1), at 5.30 p.m.—Prof. N. F. Mott, F.R.S: "Recent Work on the Theory of the Latent Image".

Royal Photographic Society, Scientific and Technical Group (at 16 Princes Gate, South Kensington, London, S.W.7), at 6 p.m.—Mr. J. F. Dunn and Mr. G. S. Plant: "A New Photometric Exposure Meter for Camera and Enlarger".

Wednesday, October 24

Manchester Metallurgical Society (joint meeting with the Institute of Metals and the Iron and Steel Institute) (at the Engineers' Club, Albert Square, Manchester), at 6.30 p.m.—Dr. R. Jackson: "The Application of Radiography to the Improvement of Foundry Technique".

Institute of Welding, Wolverhampton Branch (at the Victoria Hotel, Wolverhampton), at 7 p.m.—Mr. H. Thompson: Chairman's Address.

Thursday, October 25

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. H. Hartridge, F.R.S.: "The Direction of Flight of Bats by means of Sound Waves"; Mr. James Hornell: "How did the Sweet Potato reach Oceania?"

Friday, October 26

Chemical Society (joint meeting with the Glasgow University Alchemists Club and the Andersonian Chemical Society) (in the Large Lecture Theatre of the Chemistry Department, The University, Glasgow), at 3.30 p.m.—Sir Robert H. Pickard, F.R.S.: "Long Chain Molecules".

Bedson Club (in the Chemistry Lecture Theatre, King's College, Newcastle-upon-Tyne), at 5.30 p.m.—Prof. N K. Adam, F.R.S: "Surface Films" (Sixtieth Bedson Lecture).

Institution of Electrical Engineers, Measurements Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. S. H. Richards Inaugural Address as Chairman.

Institution of Mechanical Engineers (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Prof. R. N. Arnold: "The Mechanism of Tool Vibration in the Cutting of Steel".

Chemical Society (joint meeting with the South Yorkshire Section of the Royal Institute of Chemistry) (in the Chemistry Lecture Theatre, The University, Sheffield), at 6 p.m.—Prof. D. T. A. Townend: "Flame".

British Association of Chemists, St. Helens Section (at the Y.M.C.A. Buildings, St. Helens), at 7.30 p.m.—Mr. A. Rees-Jones. "From Lab. to Full Scale Production".

Institute of Welding, East Scotland Branch (at the Heriot-Watt College, Chambers Street, Edinburgh), at 7.30 p.m.—Mr. D. M. Kerr: "Recent Advances in Welding in the Shipbuilding Industry".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned.

Assistant Veterinary Investigation Officer—The Secretary and Bursar, Seale-Hayne Agricultural College, Newton Abbot, Devon (October 26).

Head of the Building Department of the St. Helens Municipal Technical College—The Director of Education, Education Office, Cotham Street, St. Helens (October 27).

Chemist—The Secretary and General Manager, Newcastle and Gateshead Water Co, Pilgrim Street, Newcastle-upon-Tyne, 1 (October 27).

Teacher (full-time) of Physics and Mathematics in the Department of Chemistry, Physics and Biology of the Doncaster Technical College—The Chief Education Officer, Education Offices, Doncaster (October 27).

Lecturer in Mechanical Engineering Subjects (Graduate in Engineering or with equivalent qualifications and capable of teaching to Higher National Certificate standard), a Lecturer in Chemistry (well qualified academically to undertake work to Degree standard), and a Lecturer in Building Subjects (qualified to undertake work to Higher National Certificate standard), in the St. Helens Municipal Technical College—The Director of Education, Education Office, Cotham Street, St. Helens (October 27).

Civil Engineers by Singapore Municipality. Civil Engineer to become Assistant Municipal Engineer (Roads and Bridges) (Ref. No E.1978.XA), Civil Engineer to become Assistant Municipal Engineer (Sewerage) (Ref. No. E.1979.XA), and a Civil Engineer to become Assistant Water Engineer (Ref. No. E 1980.XA)—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W C.2, quoting the appropriate Ref. No. (October 29).

Graduate Lecturer (full-time) in the Department of Mechanical Engineering of the Coventry Technical College—The Director of Education, Education Department, Council House, Coventry (October 29).

Senior Temporary Assistant (man or woman) under the Psychological Adviser—The Secretary, Civil Service Commission (Dept. O), 6 Burlington Gardens, London, W.1 (October 30).

Lecturer (full-time) of Science and Mathematics in the Department of Building and Architecture of the Liverpool Technical College—The Director of Education, 14 Sir Thomas Street, Liverpool, 1 (October 31).

Instructor (full-time) in Production Engineering Subjects at the Leeds College of Technology—The Director of Education, Education Office, Leeds, 1 (November 3).

Deputy Borough Electrical Engineer—The Borough Electrica Engineer, Shannon Street, Blackpool (November 5).

City Electrical Engineer, Salisbury, Southern Rhodesia—The Ministry of Labour and National Service, Appointments Department Technical and Scientific Register, Room 670, York House, Kingsway London, W.C.2, quoting D.1485.XA (November 6).

Fellowship in Electrotechnology, Council for Scientific and Industrial Research, Melbourne—The Australian Scientific Researc Liaison Office, Australia House, Strand, London, W.C.2 (November 9).

Assistant Lecturers in Botany, Chemistry, Mathematic Physics, Zoology and Geography—The Registrar, University College, Leicester (November 10).

Technical Translator into English from Swedish by first class electrical engineering company in Sweden, primarily for the English edition of their technical house journal—The Ministry of Labour and National Service, Appointments Department, Technica and Scientific Register, Room 670, York House, Kingsway, London W.C.2, quoting D.1498 XA (November 12).

Director—The Chairman of the Council, British Electrical an Allied Industries Research Association, 15 Savoy Street, London W.C.2 (November 16).

Lecturer in Industrial Chemistry, a Lecturer in Mechanica Engineering, and an Assistant Lecturer in Chemistry, at the University of Queensland—The Agent-General for Queensland, 40 Strand, London, W.C.2, and the Secretary, Universities Bureau o the British Empire, c/o University College, Gower Street, London, W.C.1 (November 30 in Brisbane)

Deputy Engineer and Manager of the Warrington Corporatio Water Works—The Town Clerk, Town Hall, Warrington, endorse 'Deputy Water Engineer and Manager' (November 30).

Director of Museums, Liverpool—The Town Clerk, Municipa Buildings, Dale Street, Liverpool, 2, endorsed 'Director of Museums (November 30).

Sorby Research Fellowship—The Assistant Secretary, Roya Society, Burlington House, Piccadilly, London, W.1 (December 1).

Tucker-Price Scientific Research Fellowship for research o Mathematics, Natural Sciences and allied subjects—The Secretary Girton College, Cambridge (January 15).

Instrument Makers (20) for the Telecommunications Researc Establishment, Malvern—The Exchange Manager, Ministry of Labou and National Service, Malvern.

Pathologist (whole-time)—The Superintendent, Northampto General Hospital, Northampton.

Demonstrator in the Department of Physics, and a Junio Demonstrator in the Department of Biology—The Secretary St. Mary's Hospital Medical School, Paddington, London, W.2.

Laboratory Steward for cancer research laboratory, to tak charge of animal house—The Director of Research, Glasgow Roya Cancer Hospital, 132 Hill Street, Glasgow, C.3.

Technical Librarian—The Secretary, Copper Developmen Association, Grand Buildings, Trafalgar Square, London, W.C.2.

Lecturer in Neuropathology in the University of Sydney an Neuropathologist to the Mental Hospitals of New South Wales—The Secretary, Universities Bureau of the British Empire, c/o University College, Gower Street, London, W.C.1.

Crop Recorder at the Institute's Sub-station in Hampshir (applicants should have had a sound training in agriculture and/o botany)—The Secretary, National Institute of Agricultural Botan Huntingdon Road, Cambridge.

Teacher (part-time) of Geography—The Principal, West Ham Municipal College, Romford Road, Stratford, London, E.15.

Assistant in the Department of Chemistry—The Secretary, The University, Aberdeen.

Lecturer (full-time) in Electrical Engineering (capable teaching Design of Electrical Machinery up to the Higher Nationa and London University Final B.Sc. Degree standard, together wit at least one other advanced electrical subject)—The Principal, Roy Technical College, Salford, 5.

CARE OF GEOLOGICAL FEATURES IN ENGLAND AND WALES

BRITAIN occupies a peculiarly vital position in geological science. Within its small area are examples of a great range of geological features and of rocks of almost all ages. In the development of geology, British investigators have played an exceedingly important part and have laid the foundations of many branches of study. Many parts of Britain, therefore, contain features of considerable historic interest which will long continue to be of importance to students. In general, it may seem unnecessary to give much attention to the preservation of such geological features, for in many cases they have survived for centuries, and it is not likely that future development will cause them serious harm. The case for their preservation does not always appear to be so urgent as that for the preservation of plants and animals, rare species of which may be exterminated as a result of changes in the utilization of the land. It is desirable, however, at this time, when greater attention is being devoted to the planning of the countryside, that the need for some consideration of geological monuments and sections should not be overlooked, especially as some of the sections are of importance in the progressive development of the science. It is also most essential that arrangements should be made to secure free access to these sites.

These questions have recently been considered in some detail by a Geological Sub-Committee set up by the Nature Reserves Investigation Committee and presided over by Dr. G. F. Herbert Smith. Members of the Sub-Committee included representatives of the Geological Society of London and of the Geological Survey. They have been assisted by more than forty geologists with local knowledge. The report of this Sub-Committee has just been issued*, and it may be hoped that its recommendations will be carefully considered by those concerned with the planning of national parks and nature reserves under the Minister of Town and Country Planning.

The appointment of this special Sub-Committee indicates a recognition that the preservation of geological sections requires different measures from those necessary for the protection of wild life, and the Sub-Committee has worked out its own classification of the types of area and site to which consideration needs to be given. They have defined four separate categories as follows :

(*a*) *Conservation Areas* (*Geological*). Large-scale physiographic features and areas containing many items of geological interest. Working quarries in such areas are to be registered, new quarrying or other works to be undertaken only after approval has been obtained from the appointed authority, advised by a scientific panel.

(*b*) *Geological Monuments.* Small-scale geological features and sections of outstanding interest, to be permanently protected and kept in a good state of preservation.

---

* Report by the Geological Sub-Committee of the Nature Reserves Investigation Committee. Memorandum No. 5 : National Geological Reserves in England and Wales Pp iv+42. (Society for the Promotion of Nature Reserves, British Museum (Natural History), London, S.W.7.) 1*s*. 6*d*.

(c) *Controlled Sections.* Natural sections and artificial sections in a state of disuse, to be subject to control on account of their scientific value, in order to protect them from being obscured by building or the dumping of refuse, or otherwise rendered inaccessible.

(d) *Registered Sections.* Sections of exceptional geological importance at present used or worked, to be listed and to be kept under observation by an appointed authority, the owners or lessees being required to give notice of their intention to cease operations, in which event the sections in question would be considered for transference to the previous category, (c).

In these four categories the Sub-Committee has listed 390 sites in England and Wales, arranging them under counties for convenience of reference; 331 of these sites are in England, 58 in Wales and one is shared by both countries. Of conservation areas there are 71, of geological monuments 48, of controlled sections 198, and of registered sections 73. These are large numbers; but when the lists of sections given under any county are examined, it is at once recognized that there has been rigorous selection of those sections which are recommended for control or registration, and an even more careful scrutiny has been given to the selection of geological monuments. Many quarries of great scientific importance are not listed. Moreover, the controlled sections include many stretches of sea cliffs which are not likely to be greatly affected by any changes which can be foreseen, but to which it is essential that access should continue to be available; conservation in these cases will not be costly or difficult.

The sites selected are very unevenly distributed over England and Wales, as is to be expected. They fall chiefly in areas where there are harder rocks, for these yield features which may be scenically more attractive and which are more likely to be permanent. It is doubtful, as the Sub-Committee notes, whether much can be gained by preserving a clay pit after its working has ceased. There is thus only one section indicated in Essex and only two in Hampshire, while there are twenty-six in Shropshire and forty-two in Yorkshire. It is a little surprising, however, to find only two each in Cardiganshire and Carmarthenshire. It may be hoped that some sections in the classic areas of Llandeilo and Llandovery in the latter county may be found suitable for conservation.

When the large number of the suggested areas is being considered, several points must be borne in mind. In the first place, many will probably fall within areas which will be utilized as national parks. It may be hoped, therefore, that it will be easier to effect some measure of control. Others will probably overlap with conservation areas chosen on biological grounds, and obviously much is to be gained where the purposes of both biology and geology can be served by the conservation of single areas. Moreover, many of the sites suggested as monuments and as controlled and registered sections fall within the wider conservation areas.

There is clearly a distinction between the problems of registration and control of sections and monuments and the provision of access to them on one hand, and the conservation of large-scale features containing many items of geological interest on the other. In the case of monuments and sections, little supervision is necessary; and provided that access can be secured, little more than periodical inspection is required. It is to be hoped that in such cases a descriptive label (the Sub-Committee suggests in the form of a metal plate) would be set up. There is little doubt that this would have great educational value. Many of the geological monuments listed, such as the Bowder Stone in Borrowdale and Durdle Door, west of Lulworth Cove, are already visited by great numbers of walkers and others. An indication of their significance and of the fact that they are of national interest would do much to stimulate a greater attention to geological phenomena.

The conservation areas suggested by the Geological Sub-Committee involve tracts of country, some of them very small, others covering considerable areas. They include such features as Incombe Hole, Ivinghoe, Bucks, the Lizard Peninsula, four tracts in Derbyshire and six coastal regions in Dorset. It is rather surprising to find that no areas are specified in Cumberland, though it is possibly anticipated that the Lake District will be covered by a proposed national park. Some of the areas included are of physiographical as well as geological interest; and it would be valuable to consider the addition of other physiographic types, such as some areas in the Norfolk Broads or the Fens, and other coastal features such as Chesil Bank, which is conveniently near an area already specified as a controlled section.

The Sub-Committee holds the view that such geological conservation areas should be kept, so far as possible, in their present condition. They do not suggest that quarrying and other industrial activities should cease, for they recognize that the geologist gains greatly from the working of quarries. It is indeed obvious that in many cases more may be gained by continued working of a quarry than by the preservation of a particular section in its present condition. On the other hand, it may be possible to secure the preservation of a column representative of an important section revealed in the course of quarrying operations.

The Sub-Committee indicates that the list which it has provided is not to be regarded as final; and it is engaged in the preparation of a second list of sites and sections of less general interest, some of which it suggests might be preserved by local action. It is desirable that local patriotism should be roused for the protection of many of these features, and that their educational value should be made more widely known.

The conservation of these sites is not only of educational value, however. While it may be hoped that the control of monuments and sections would direct the attention of a wider public to the existence and terest of most of these features, it must be emhasized also that many of them are of vital importce for scientific research. Moreover, it may be ped that the conservation of these features will ing enjoyment and stimulus to many who are terested in the countryside but who have no special owledge of geology. One valuable aspect of the nservation of such features is that it involves no strictions on the general public. Whereas it may necessary in the case of some nature reserves to mit access, in the case of geological reserves all that required in most cases is to secure that access mains available for geologists as well as for other sitors. The protection of many of these features ould thus increase and safeguard the general nenities of the countryside for the public as a hole.

It will be noted that the present report refers to ngland and Wales only. Similar questions are being alt with separately in relation to Scotland, where may be hoped that comparable steps will be ntemplated.

LANT LIFE AND SOLAR ENERGY

hotosynthesis and Related Processes

y Eugene I. Rabinowitch. Vol. 1: Chemistry of hotosynthesis, Chemosynthesis and related Prosses in Vitro and in Vivo. Pp. xiv+599. (New ork: Interscience Publishers, Inc., 1945.) 8.50 ollars.

THIS book is an outstanding contribution to the problem of photosynthesis, and is the first volume a work which will deal with this fundamental hysiological process from the chemical, physical and otanical points of view. The author is a research sociate, Solar Energy Conversion Research Project, assachusetts Institute of Technology, and explains at while this work is not concerned directly with hotosynthesis "it has helped to keep alive an interest the subject, for while experimenting on the conrsion of light energy into chemical energy one nnot but turn continuously to plants and wonder w Nature has achieved a result which has not been proached in the laboratory".

This volume is divided into two parts, the first aling with the chemistry of photosynthesis and lated processes, and a second part dealing with e structure and chemistry of the photosynthetic paratus. These are preceded by two introductory apters, one concerned with the role of photonthesis in Nature and the second with the discovery photosynthesis. Both these chapters might be ad with great interest by the general reader. It is range that although this process is so fundamental the existence of all life it was not discovered until e eighteenth century. Since then investigations ve increased at a great rate in all countries, and the present time the literature on this subject in ientific journals is immense. It is contained in otanical, chemical, physical, agricultural and physiogical journals, so that the preparation of a complete bliography is a formidable task. Dr. Rabinowitch s gone far in achieving this, and every part of e present volume is well documented and every apter contains a bibliography; the one following chapter 10, for example, quoting more than 250 references from 1843 until 1940. The great amount of literature brought together and discussed makes this work of great interest both to chemists and to physicists.

Each of the two parts of the present volume is divided into a number of chapters dealing with different phases of the subject. The first part is subdivided into ten chapters and each into many sub-sections. Dr. Rabinowitch first treats of the over-all reaction and the products of photosynthesis and then goes on to consider related processes outside the living cell. Then follow chapters dealing with the photosynthesis and chemosynthesis of bacteria and the metabolism of anærobic bacteria, with a significant section on the role of autotrophic bacteria in Nature. "Green plants reduce carbon dioxide in light by means of water; green and purple sulfur bacteria reduce carbon dioxide also in light by means of hydrogen sulphide; colourless sulfur bacteria reduce carbon dioxide by means of hydrogen sulphide without light. This comparison shows the existence of a hierarchy of autotrophic organisms and encourages speculations as to the genetic relationships between them." This leads on to a discussion of the primary photochemical process of the oxidation of water as the first stage and the reduction of carbon dioxide as the primary process. In a subsequent chapter we have a discussion on the assumption that the reduction of the complex carbon dioxide is a non-photochemical process involving an intermediate reductant and not a photochemical reaction with reduced or excited chlorophyll. Later chapters deal with inhibition of photosynthesis by chemical and physical agents.

In Part 2, which is concerned with the structure and chemistry of the photosynthetic apparatus, one of the most interesting chapters deals with the structure, composition and pigments of the chloroplasts and chromoplasts. The revival of the hypothesis of chlorophyll grana in 1932 and its confirmation by photographs by Doutreligue in 1936 is described. This confirmation showed that the grana are distributed more or less uniformly throughout the chloroplast in distinction to the earlier views that they were concentrated on the surface. Later chapters deal with the chlorophylls *a* and *b* and their ratio; the chlorophylls of the algæ and the concentration of chlorophylls in leaves. The molecular structure and chemical properties of chlorophyll form an important section and the latter part of Part 2 is devoted to the accessory pigments such as the carotinoids, phycobilins, flavones and anthocyanins. Then follow chapters on the photochemistry of pigments *in vitro* and *in vivo* and the last chapter discusses photosynthesis and respiration.

Dr. Rabinowitch raises the question of a possible connexion between the two catalytic mechanisms, and observes that while the nature of the links is as yet quite uncertain they will undoubtedly be subject to closer study in the near future. He follows this up by quoting observations on the effect of light on respiration and observes that "none of the experiments described provides a final proof of the non-existence of true 'photorespiration', the least that can be stated is that no evidence of such a phenomenon has as yet been found (except perhaps in ultra-violet light), and that all definitely established cases of light stimulated respiration were of the 'persistent' type, and could be attributed either to an accumulation of sugars or to an indirect photochemical effect of blue-violet light absorbed by the carotenoids".

This book differs from previous works on the subject by the greater emphasis on physical and physico-chemical theories and methods due to the newer trends in the study of photosynthesis. Photosynthesis in relation to systematic botany or ecology has little place in it. It is essentially written for the research worker and should greatly stimulate work along these lines. The important literature from all sources is brought together and discussed and the book thus forms a very notable addition to the literature in this field. The appearance of Vol. 2 will be awaited with interest.

F. J. LEWIS.

MEDICINE AND THE HUMANITIES

The Art of Medicine in Relation to the Progress of Thought

A Lecture in the History of Science Course in the University of Cambridge, February 10th, 1945. By A. E. Clark-Kennedy. Pp. 48. (Cambridge: At the University Press, 1945.) 2*s.* net.

THIS lecture, written in simple words and infused by a contemplative charm, is not designed to answer the age-old questions: Have we a soul? What is mind? and so forth. It briefly discusses these questions and suggests to us why they cannot be answered and why they probably never will be answered. But the purpose of the lecture is rather to consider how medicine, by bringing science and thought into intimate and personal relationship with humanity, "has resulted in science making a greater contribution to thought than otherwise would have been the case".

In his brief history of the development of medicine and his longer one of the developments of the last hundred years, the author gives, in a short space, a valuable dissertation on his general theme. Prominent in it is the new conception of disease which has arisen, a conception which is an advance upon Sydenham's useful conception of clinical entities, which has, the author thinks, tended to obscure the real nature of disease and to lead to a superficial attitude to problems of medical practice. In a similar way, it might be added, too much emphasis in all fields of inquiry on useful and, indeed, necessary, classification can have a similar effect. The medical man, however, is faced with problems of the mind as well as with those of the body. The body, says the author, has evolved as a physico-chemical machine. Within certain limits it influences and is influenced by the mind. To this the medical man must add the influences of genetic and environmental factors upon the production of disease; and consciousness, as distinguished by the author from the more general and unsatisfactory term 'mind', brings problems of pain, of deliberate thought and free-will and of moral and æsthetic judgment. Man is learning rapidly how to gain health, but is free, as the practising physician knows so well, to make himself as well or ill as he wills. The difficult problems for the medical practitioner which result from this and the repercussions of this view of disease upon politics, social planning, preventive medicine and State control occupy the bulk of this lecture.

On the whole, the author successfully sketches, in the brief space available to him, the main complexities of the modern medical outlook. Only here and there will the reader sit up and blink a little—as, for example, when he reads that, since the studies o Vesalius, Harvey and Malpighi, biology "has limpe along behind the mechanical sciences in the part worn clothes of her elder sister, physics". The autho seems to be quite unaware that biology has recentl undergone a change not dissimilar from that whic he indicates in medicine. The causes, indeed, o the changes in these two related fields of inquir are, and perhaps must be, essentially the same Many readers will, however, no doubt agree that th psychologists, even those who labour so earnestl and passionately to heal the disordered mind, hav nothing to guide them but an imperfect understandin of the normal mind. It sometimes seems, indee that the sick minds studied by the medical psychologist have within them a capacity for self-destructio and for the destruction of society which is analogou to that contained by the unstable isotope of uraniu used to make the atomic bomb. But does the psychologist know the stable isotope? If he does *not*, upo what does he base the theories of human educatio and conduct which are put forward for the directio of our youth and our society? The medical psychologist can, of course, not be blamed for this lack o knowledge of the norm; he is straining every nerv all the time to construct it. The only prematur thing is that our future should be subject to an form of directive whatever which is still immatur and uncertain of its foundations.

To return, however, to the main theme of thi book, its main conclusions are that there is too muc specialization in medical education (a point which i already widely recognized), and that the purely scientific education which medical students now receive is not enough for a profession which has to deal with human life and experience as a whole. I is half the art of medicine, says the author, to adop a reasonable and practical attitude to the unknown The power of modern medicine to prolong life, to relieve suffering, to influence endocrine secretion, to control birth, to dominate mind and even to modif personality is likely to increase; it should not b diminished; but in it there is a real danger. "There always is danger in power."

We live in an age when excessive anxiety ove the health of the body has replaced pre-occupatio with the welfare of the soul. Many problems, nov decided upon ethical grounds, will, in the future, b decided entirely upon grounds of medical expedienc and judgment. To meet this situation medicin could and should, the author thinks, be the connecting link which would reconcile the conflicting point of view of the humanities, on one hand, and th sciences on the other. Disease is not entirely geneti or environmental in origin; behaviour is not a conditioned reflexes and is not entirely due to deliberate thinking. There is a happy mean betwee too much individual liberty and too little externa control; too great risk and too little security; to much pain and too little suffering. Medicine has no yet displaced the notion of the soul, and probabl it never will. It is not irrelevant to remember tha it is one of the privileges of medicine to handle th biological phenomenon of death, "and here we com into closest touch with the spiritual aspects o human life".

There should be few scientific readers who wi not, if they look sincerely into their experienc endorse and welcome the main argument of th thoughtful and thought-provoking book.

G. LAPAGE.

Vegetable and Fruit Growers' Conferences

Edited by Dr. D. H. Robinson. Pp. 64. (Worcester: Littlebury and Co., Ltd., 1945.) 6*s*. net.

THIS little book consists of fourteen short papers read to the Vegetable and Fruit Growers' Conferences held in Worcester in December 1944. The ontributors are prominent commercial growers and members of research station and Ministry of Agriulture staffs.

The first paper, by Dr. H. V. Taylor, gives an account of the expansion of vegetable production during the War and probable future requirements. The second, by G. H. Tawell, deals with artificial irrigation of vegetable crops and gives useful guidance on methods, and the application of fertilizers in olution. Prof. T. Wallace contributes the next three pages on the factors determining soil fertility, and a single page by Prof. G. E. Blackman deals with the chemical control of weeds. D. R. Bomford makes a convincing plea for research on horticultural as distinct from agricultural machinery, and suggests specifications of various implements. J. F. Bomford calls for a compulsory marketing and distribution scheme and the education of urban populations in the importance of the industry and its problems. The next four papers, by N. H. Grubb, J. Turnbull, C. P. Norbury and F. J. Masters respectively, give the merits and defects of the main commercial varieties of soft and tree fruits. V. L. S. Charley discusses varieties of apples and pears for cider and perry making and of soft fruits for syrup production. G. A. Nott makes out a case for the production of unfermented apple juice as a means of disposing of low-grade fruit. D. A. Osmond writes on the soil series to be found in Worcestershire and their suitability for various crops, and the book ends with an account by W. L. Moore of his experiences in planting a cherry orchard under grass.

The papers provide stimulating thumb-nail sketches of subjects of current importance to commercial growers, and those on fruit varieties should be particularly useful. There are a few minor typographical errors.

W. E. B.

Time, Number and the Atom

By R. Fortescue Pickard. Pp. vii+92 (London: Williams and Norgate, Ltd., 1945.) 8*s*. 6*d*. net.

MR. PICKARD is interested in numbers, particularly primes and perfect squares. He points out that the ratio of the masses of the proton and the electron may be taken as 1849, and this is the sum of the consecutive primes from 3 to 131 inclusive; or as Mr. Pickard prefers to put it, the mass of the whole hydrogen atom is 1850, which is the sum of the first 32 primes, 2 being omitted. In an appendix he gives arguments in favour of omitting 2 from the list of primes. He also points out that $1849 = 43^2$, and 43 is the sum of the terms in the bracket when the Rydberg Series is taken as far as corresponds to the completed series of the Periodic System.

A search for further arithmetical relationships leads him to regard each element as characterized by two integers, its atomic number and its mass number. On account of the existence of isotopes it becomes necessary to choose a "primary" mass number, which is often the rounded atomic weight, or the mass number of the most abundant isotope, but may be that of a rarer isotope, or even of an isotope as yet undiscovered: for example, $\mathrm{Li} = 6$, $\mathrm{B} = 10$, $\mathrm{Sc} = 44$. From this array of numbers Mr. Pickard produces some interesting patterns, though as these mostly involve the sums of the mass numbers of groups of consecutive or otherwise related elements, it is difficult to see what physical significance they can have.

The word "time" in the title refers to certain metaphysical arguments tending to identify the fundamental ideas of time and number.

F. J. GARRICK.

Astronomical Air Navigation

A Comprehensive Handbook embodying the Latest Principles for Practical Navigators, Instructors and Students. By Squadron-Leader Ronald Hadingham. Second edition, revised and enlarged. Pp. xii+152. (Kingston Hill: Technical Press, Ltd., 1945.) 12*s*. net.

THE second edition of Squadron-Leader Hadingham's handbook on astronomical air navigation has been enlarged and revised. A description is included of the Mark IXA bubble sextant, with which the navigator continues his observation for two minutes, during which period the altitude is recorded sixty times and the average value of the observed altitude is automatically indicated; the accuracy of observation during unsteady conditions of flight is thereby considerably increased. A full description is also given of the astrograph and its uses; with this instrument, which was for long on the secret list, the position lines for different altitudes of two stars suitably placed for observation are projected on to the navigator's chart, enabling the position of the aircraft to be obtained quickly and without computation. The chapter dealing with star identification has been enlarged.

The volume is a useful and essentially practical handbook. It is somewhat marred by a number of loose statements, such as that "the value of refraction is always negative and must be subtracted from the observed altitude", and that "this gradual change (i.e. precession) must also produce a change in the positions of the seasons". The statement, on p. 83, that the earth's axis is inclined at 23½° to the plane of its orbit is so obviously incorrect that it is not likely to be misleading.

The Annual Register

A Review of Public Events at Home and Abroad for the Year 1944. Edited by Dr. M. Epstein. Pp. xii+506. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1945.) 42*s*. net.

WITH unfailing regularity, unbroken since 1758, this volume presents a year of the history of the world and a survey of progress in art, literature, science and finance. The usual arrangement is maintained, beginning with a summary of English political history and the course of the War, followed by imperial history; and then the most important movements and events in foreign history, which reveal much that may have been lost sight of in the limited space of current newspapers. The second part includes a chronicle of events, obituaries of the year and retrospects of various aspects of national life. Public documents printed in full include the Bretton Wood agreements, the Franco-Soviet treaty and the Dumbarton Oaks proposals. An excellent index facilitates the use of the volume. No student of current affairs can afford to dispense with this full and objective survey of the world's history.

ACOUSTIC CONTROL IN THE FLIGHT OF BATS

By Prof. H. HARTRIDGE, F.R.S.
St. Bartholomew's Hospital Medical College

NO one interested in wild life or in the science of flight can fail to be curious about bats, which in skill of manœuvre and fearlessness excite our admiration. The facts that their flight is as technically perfect in complete darkness as it is in daylight, that their wings are entirely different in design from those of the birds, and that, unlike most living creatures, they sleep hanging head downwards, add greatly to our interest in them. Small wonder if to the superstitious or the ignorant of bygone days they appeared to be guided, controlled and protected by the Prince of Darkness himself.

The hypothesis which I advanced in 1920[1] to explain their adjustment of speed and direction when flying at night was "that bats during flight emit a short wave-length note and that this sound is reflected from objects in the vicinity. The reflected sound gives the bat information concerning its surroundings. It is possible that if a bat makes use of short-wave-length sound it would be able to estimate the position in space of an object ahead of it with considerable accuracy". There seems to be little room for doubt that this hypothesis is correct, for Galambos and Griffin[2,3] found that bats while in flight emit a discontinuous supersonic note. They can steer clear of obstacles, even thin carpet thread (Hartridge), or thin wire (Hahn[4]), when flying in complete darkness provided they can emit this note and receive its reflexion from surrounding objects by their ears. If, however, they are made mute or deaf they run into such obstacles.

It is the object of this communication to try to elucidate the details of this localizing mechanism, for there are a number of disconnected observations concerning it which can now be fitted into position.

Sounds Produced by Bats

If a physicist were asked to design the vocal apparatus for a bat he would, I think, decide that this should be capable of producing two different kinds of sound: one for the purpose of avoiding obstacles while in flight; the other for sending messages to neighbouring bats, because, as will be seen shortly, no single sound would be suitable for both these purposes.

For localization, an interrupted supersonic tone is required with short wave-length and constant intensity. The interruptions should be made in such a way that the change from emission to silence and vice versa is as sharp as possible. The number of interruptions per second should be variable so as to secure the optimum conditions for localization.

For signalling, on the contrary, a supersonic tone would be quite unsuitable, for a signalling tone should not cast sharp shadows, should be as non-directional as possible, and should have very good carrying power. If possible, it should be capable of alteration in pitch, intensity and quality, for these variations would be useful when one bat wants to inform other bats about such things as the discovery of food or the approach of danger. For such a purpose a tone of medium pitch is indicated.

The bat's vocal apparatus should then be capable of producing these two different kinds of tone, and both would fall with advantage within the range frequencies for which the bat's cochlea is mo sensitive. In man this range is not very large, for extends over only about four octaves of the whol audible gamut of about 10½ octaves. Assumin that the bat's cochlea, which is histologically ver similar to that of the human cochlea, is not ver different in performance, then the localizing frequenc and the signalling frequency should not be separate by more than about four octaves, that is, the rat between them should not exceed 16 to 1. In fac the frequency of the localizing tone in bats is betwee 45,000 and 60,000 cycles per second and that of th signalling tone is roughly 7,000 cycles per second, s that their ratio is about 7 or 8 to 1—probably we within the efficient range of the bat's cochlea. If th is so, the overtones of the signalling tone would b well heard by the bat, for its first four harmonic would fall within the optimum range of bats' hearin Other important points are that the production either localizing or signalling tone, or in emergencie both at the same time, should not interfere at a with flight. Neither should the production of th localizing tone interfere with the collection of foo since a bat's flight is largely, if not predominantl used for that function. Lastly, the localizing ton should be capable of continuous production, not, fo example, having to be stopped during the inspiratio of fresh air into the lungs.

Bats produce four different kinds of sound: (1) buzz. This is not audible unless the observer is quit close to the animal. (2) The signalling tone of abou 7,000 cycles per second. This usually lasts for quarter of a second, and may be repeated over an over again. (3) The supersonic tone. This is seldo less than 30,000 cycles or more than 70,000 cycle per second in the majority of bats. It usually lie between 40,000 and 55,000 cycles. This sound ma be emitted both when at rest and in flight. It ma be emitted once only, as a single pulse, when it last for about 0·01 sec.; or a number of such pulses ma be produced. At rest a bat may produce five to te supersonic cries per second. When it begins to fly the rate is increased to twenty or thirty per second When, however, obstacles lie immediately ahead, th number may be raised still further, to as many a sixty per second for short periods. (4) A click whic is usually audible anywhere in a small room.

Both the buzz and the click are accompanied b the supersonic tone described above. In the case o the click, there is a single short output of supersoni energy. In the case of the buzz there is a continuou evolution of the interrupted supersonic tone. I should be noted that whereas the click and buzz ar always accompanied by supersonics, the signallin tone may either be produced by itself or be accompanied by the supersonic tone.

Structure of the Throat of Bats

The structures in the bat by which the four differen types of sounds are probably produced will now b considered. The production of these sounds mus not interfere with either breathing or flying. Neithe must they make the catching of food difficult, fo this is one of the objects of bats' flight. The utilizatio of energy by the vocal apparatus must be inconsiderable, and the air passages to the lungs must no be obstructed. In addition, it would be advantageou if the vocal apparatus were small in size and ligh in weight. In all these respects it would be difficult to select a more compact and versatile mechanism than one on the plan of the mammalian larynx. In man this usually has a range of about two and a half octaves, but may extend to nearly three and a half octaves. Now, apart from the click, the three sounds produced by the bat have frequencies of 12–60 for the buzz; about 7,000 cycles per second for the signalling tone; and about 50,000 cycles per second for the supersonic tone. So different are these frequencies that it seems most unlikely that they could all be produced by the vibration of a single vocal mechanism adjusted to different tensions, masses and lengths. That two mechanisms at least are involved is probable from the fact that the buzz and the supersonic tone occur at the same time. If they were both made by the same structure, it would be necessary for the supersonic vibrations to be quenched either by greatly increasing the tension in this structure, or by allowing it to become quite slack, or by forcing its vibrating parts into contact. Each of these changes would cause an alteration in pitch to occur just prior to the beginning of the silence, and again at its cessation. But no such changes are shown in the records obtained by Galambos and Griffin. We are therefore led to the conclusion that the buzz and the supersonic tone are produced by different structures.

It is much more difficult to reach a decision with regard to the origins of supersonic and signalling tones. Since their frequencies are in the ratio of about 7 to 1, that is, within three octaves of one another, they could without difficulty be produced, one at a time, by the same vibrating structure. Some bats have been observed to produce both these tones at the same time; and it is stated that certain species of bat have two separate vibrating structures in their larynx. If these observations are confirmed, it is possible that one of these structures produces the signalling tone and the other the supersonic tone.

The position may be summarized as follows: The larynx of the bat contains at least two and possibly three vibrating structures. If two only, then one is used for the buzz, the other for both the supersonic and the signalling tones. If there are three, then the buzz and these two tones may be separately produced.

With regard to the position of these structures in relation to one another, they might be arranged either in series or in parallel. But since the buzz is used to modulate the supersonic tone, the series arrangement seems to be preferable. The air from the lungs will therefore pass through the first mechanism and then through the second, setting both of them into vibration.

The laryngeal mechanism for producing either the signalling tone or the supersonic tone might be similar to that of the normal mammalian larynx, except that for the latter greater tensions must be associated with vibrating members of small length and mass, attached at either end to exceptionally rigid supports. This conclusion fits in with the anatomical observations of Robin[5] and Elias[6] on the bat's larynx. They point out that in many places bone has replaced the more usual cartilage. They also emphasize the massiveness of the muscle bellies which set up the tension in the vocal cords. There seems to be little room for doubt that the bat's larynx is generally similar in design to the human larynx, and that it has the same mode of operation, but that it has been greatly modified in detail in order to produce the very high frequency tones required by the bat for its special purposes.

The laryngeal mechanism for producing the buzz may be constructed on similar lines to the above, but its low frequency (12–60 cycles per second) makes an alternative method possible, namely, a rhythmic opening and closing of the orifice, through which the air stream is passing, by direct muscle action.

There is one obvious difficulty in accepting such a suggestion, namely, that mammalian muscles do not as a rule contract rhythmically at such a very high rate as sixty times per second. Thus Ching and I[7] found when flexing and extending the right forearm that eleven up and down movements could be made per second. Fenn[14] obtained values of six to ten movements per second.

It may be pointed out, however, that the wings of insects are moved at very high rates by muscles histologically similar to human striated muscle, the rates of vibration in some cases being hundreds per second. It is therefore possible that certain muscles in a bat may also have a high rate, up to 60 vibrations per second.

If this is the case, it makes possible a linking of two muscle actions, one quenching the supersonic tone, the other rendering the ear insensitive to supersonic sound. This most desirable arrangement will be discussed later.

With regard to the actual structures which produce the buzz, one possible suggestion is the false vocal cords. These are situated in an anterior position to the true cords and are under the control of the will. Normally they are separated; but they are brought together during swallowing and also when the breath is being held for some violent muscular movement. They are first brought together and then separated for coughing. They might be modified for the production of the buzz by an increase in the rapidity of opening and closing under muscle action. The fourth type of sound made by a bat—the click—may be produced by the same structures, namely, by bringing them together, raising the air pressure in the lungs, separating them suddenly (during this phase the supersonic tone is produced), closing them again, reducing the air pressure in the lungs to its normal value and then separating them once more.

The Supersonic Tone

If a supersonic tone were being selected for purposes of localization, there are two physical factors which would have to be taken into account: the attenuation of sound during transmission through the air, and the resolving power that is required. As with optical instruments, so with devices using sound waves for purposes of localization, the shorter the wave-length the finer the structure the presence of which can be identified. In order to detect the presence of thin wires or threads, wave-lengths approaching the diameters of the wires would be required, the shorter the better. The use of sound of very short wave-length may lead, on the other hand, to much less effective results, owing to the attenuation of sound during its transmission through the air.

The volume of sound reflected back from a small obstacle at first improves with decrease in wave-length, but as attenuation comes into play the improvement ceases and is replaced by a falling off of efficiency.

The resolving power, other things being equal, increases in proportion to frequency, whereas the attenuation increases as the square of the frequency. The following values show how important the effect of attenuation is: at 200 cycles the distance at which the original intensity is reduced to 36·8 per cent is 1,000,000 metres; at 10,000 cycles the distance is

410 metres; but at 100,000 cycles the distance is only 4 metres. If, therefore, a bat emitted a note of the latter frequency, only 36·8 per cent of the sound intensity would reach 4 metres, and only 13·5 per cent would be present at 8 metres. Thus a bat 4 metres from an object would receive back from that object only 13·5 per cent of the sound which it emitted, assuming that the whole of the sound emitted reached the object and all of it was reflected back again into the bat's ears. Such, of course, is not the case; for in the first place there is a loss due to the radiation of the sound waves from the source, and in the second place there are the losses which occur when the sound is reflected. The smaller the object, the greater the latter losses become. With reduction of wave-length (increases of frequency) the losses by reflexion become less, but the losses by attenuation become greater. The case is not very different from that of the microscope, in which the shorter the wave-length of the light the greater is the resolving power; violet rays giving greater resolution than blue rays, and ultra-violet rays greater than violet ones. A limit is, however, soon reached owing to the attenuation of the rays by the optical media of which the lenses of the instrument are constructed. If all the facts concerning the vocal apparatus, the behaviour of the sound waves, and their reception by the ears of the bat were known, it is not unlikely that it would be found that a frequency of about 50,000 cycles per second would give an optimum effect.

Having discussed some of the physical limitations of the use of sound for purposes of localization, we may now consider the successes and failures of the method in practice. It enables the bat to steer clear of carpet thread[1] and wire[4], and to determine the differences between such objects and flying insects, since the bat steers away from wires, but towards insects. It gives the bat precise information regarding the sizes of openings so that it can decide whether a safe passage can be made or not. As would be expected, it fails to identify the presence of a fine mesh net or of a mass of fine material backed by a solid object (hair on a person's head). On the whole, it appears to be a wonderfully successful sixth sense for all conditions which a bat encounters in its natural state.

Interruption of the Supersonic Tone

A problem which deserves consideration concerns the interruption of the supersonic note. How is this interruption produced? Is it done intentionally or accidentally? If intentionally, what use is made of it by the bat?

That the interruptions are intentional is shown by two facts: (1) bats can produce an uninterrupted note (usually of about 7,000 cycles per second); and (2) the rate of the interruptions when these are present can be varied, being increased when obstacles are close ahead and reduced again when such obstacles have been safely negotiated. The benefit to be obtained by varying the rate will be considered shortly.

That the interruptions serve a valuable purpose can readily be understood by considering the case of a continuous note, which is reflected without cessation from surrounding objects into the bat's ear. These reflected waves will usually be far weaker than the source itself, particularly when they come from small objects like threads, wires or flying insects. In consequence, while the source itself is sounding, these weak reflected waves may easily fail to be observed. Particularly would such be the case if the source were placed close to the ears in the same animal. By the use of an interrupted source emitting short pulses of sound waves, these difficulties are avoided; since the reflected waves will reach the ears between the pulses of emitted sound waves, that is, during the silent intervals. Two things are obvious: that the source of the sound must be shut off as sharply as possible, in order not to interfere with the reception of the reflected waves; and that it is beneficial to increase the rate of the interruptions as an obstacle ahead gets closer and increased accuracy of localization is required. It is probably for this reason that bats increase the rate of the interruptions when critical steering is necessary.

Bat's Hearing

The cochlea of the bat is histologically similar to that of other mammals, but in several important respects it has been adapted for special uses. Thus it is cast at a higher frequency. Whereas the audible limits for man are from about 16 to 16,000–20,000 cycles per second, those for the bat were found by Galambos to be from 30 to 98,000 cycles per second. Further, whereas the hearing of man falls off in acuity with increasing steepness above about 5,000 cycles, the hearing of a bat is still acute at 60,000 cycles.

The middle ear of the bat has a particularly well-developed reflex called by Galambos the intra-aural muscle reflex[6]. This consists of the contraction probably of both the tensor-tympani and stapedius muscles. This reflex has an inhibiting effect on sound transmission through the middle ear. Galambos found that as a bat dies there is, roughly five minutes after respiration has ceased, a marked rise of the cochlea potentials which are produced by intense supersonic tones. A similar change occurs after administering curare. He interprets these facts as follows. That there is a reflex in normal bats reducing the audibility of intense supersonic tones. In consequence, when this reflex is abolished by paralysing the muscles concerned, either by asphyxia or curare, there is a rise in intensity of the sound heard by the animal.

If Galambos' interpretation of his experimental results is correct, this reflex should be a valuable feature in the sound-localizing apparatus as a whole.

One of the difficulties of the process is that the intense supersonic cry produced by a bat may prevent the recognition of the faint sounds which are reflected back from neighbouring objects. The sudden interruption of the supersonic tone as described above will obviously be a valuable aid in this direction; but this would be even more effective if the bat's ear could be rendered quiescent, or partially quiescent, during the time that the supersonic tone is being produced.

The suggestion has been put forward previously that the supersonic tone may be interrupted by direct muscle action. If the ears of the bat could be rendered less sensitive by muscle action, then these two sets of muscles (those of the larynx and those of the ear) being synchronized, one would have the optimum conditions for sound localization. When the supersonic tone is sounding, the ears would be deaf; and when the supersonic tone is silent the ears would be returned to full sensitivity. Such an arrangement would be of the utmost benefit to the bat. Further research will obviously be required before such a hypothesis could become acceptable.

A further point which deserves mention concerning the auditory apparatus of bats is the very great development of the pinna, which in most species of bats extends like a large flap from the side of the head, the wide open mouth of the pinna pointing in a forward direction.

There is little doubt that a bat can hear quite well when the pinna has been removed, or when this has been replaced by a short length of glass tubing. At the same time, there seems little doubt that an intact pinna adds greatly to the sensitivity of the ear for the reception of sounds coming to the bat from objects ahead of it.

An important function served by the two ears is to provide stereophonic reception. In man this enables the position of objects which are producing sound to be identified with considerable accuracy. Two methods are employed: with low-pitched tones the time of arrival of the sound waves at the ears is the criterion which is used, the nearer ear receiving the sound first; with high-pitched tones intensity plays the major part, the nearer ear receiving the stronger stimulation. With medium pitched sounds both methods are employed[12].

We do not know how bats use their ears for purposes of localization; it may be by time of arrival, by intensity, by phase, or by change of quality.. That the two ears used together play an essential part is shown by the experiments of Galambos and Griffin. "With one ear covered a bat strikes our type of wire barrier almost as frequently as when it is completely deaf." . . . "A few bats refused to fly at all when one ear was covered. Usually such bats land normally on the wall instead of bumping it. They often turned back from the wire or wall, while totally deaf bats practically never did so. This indicates that one ear is sufficient to inform the animal of the general proximity of a large obstacle, but that fine discriminations are almost impossible".

The conclusions that we seem to be justified in reaching as a result of these experiments is that the supersonic beam which a bat emits during flight is reflected (usually in all directions) by external objects. Some of these reflected waves reach the bat's ears and then, by some means at present not known, enable the bat to localize the position of these objects.

Transmission of the Supersonic Note to the Air

Having dealt with the supersonic tone and the probable structures by which it is produced, the following question requires an answer. How is this supersonic tone transmitted to the air? Is it via the nose only, via the mouth only, via either nose or mouth, or via both at the same time?

The facts at our disposal appear to be as follows. Bats have their mouths open during flight. Galambos and Griffin found that if bats are gagged by having a loop of thread tied round their snouts and collodion applied to their lips, the ability to produce the interrupted supersonic note is usually, but not always, seriously impaired, or stopped altogether. When the latter is the case, they fly in a clumsy, hesitant and bewildered manner not noticeably different from that of deafened bats. One bat (No. 37) was an exception, however, for it produced the supersonic note sufficiently well through its nose for it to be recorded electrically, and the flight of this bat was not seriously affected by the gagging[9]. These facts taken together strongly suggest that the supersonic note is usually emitted by the mouth, but may exceptionally be emitted in sufficient strength through the nose.

If this conclusion be correct, it would be expected that breathing would also take place during flight principally via the open mouth and only to a slight extent, if at all, via the nostrils. But there are two facts which make this idea unlikely, or even impossible. (1) Spallanzani[10] found that when the nostrils of bats are plugged they experience acute respiratory embarrassment when in flight, even though their mouths are available for breathing. (2) Most kinds of bat feed on night-flying insects such as mosquitoes, small moths and the like. One object of a bat's flight is therefore to collect food. Since its limbs are being employed for flight, it has to do this with its mouth, which it opens widely for this purpose. The back of the mouth—the fauces—must be kept shut, for otherwise an insect, or part of an insect, might enter the passages by which air gains access to the lungs and cause coughing. If this took place during flight it might have serious consequences, since the supersonic tone would temporarily have to be stopped.

The mouth must not, therefore, be used either for breathing or for the emission of the supersonic tone while it is being used for catching insects. Apart from insects, other foreign bodies float about in the air, for example, parts of plants, and these would be a source of danger to bats if they could pass via the mouth into the air passages. For these reasons the mouth cannot be used for breathing or phonation, and the nose must be used instead for both. This accounts for the finding of Spallanzani that blocking the nostrils caused acute respiratory embarrassment during flight.

How is this conclusion to be reconciled with the experiments of Galambos and Griffin that closing the mouth stops the supersonic tone in most, but not in all, bats?

I think the explanation is as follows. Bat No. 37, which they thought to be the exception, was in fact the rule, and it was the other bats which were the exceptions. This bat could both breathe and phonate, although its mouth was sealed completely with collodion, and in consequence of producing normal phonation its flight was normal. What is the explanation of the behaviour of the other bats which, when their mouths were closed, failed to phonate and therefore failed also to fly without accident? A possible explanation is that they had some nasal defect such as a cold in the head. Such a defect is common in animals kept in captivity, as these bats were.

Assuming that the correct conclusion has been reached about the emission of supersonic sound by the nose, one further point may be mentioned. The snouts of many species of bat are so shaped that they may enable them to produce a kind of beam of supersonic sound energy[13], or at all events may direct the greater part of sound in a forward direction away from the bat's own ears. This would have the effect of improving both the intensity of sound reaching obstacles ahead of the bat, and the sensitivity of the bat's ears.

The Breathing of Bats

Galambos and Griffin have raised an important question when they ask how breathing occurs during the continuous production of the interrupted supersonic tone. That this tone is produced by the vocal apparatus of the throat, and not, for example, by wing vibrations, is shown by their experimental result that bats immersed up to their necks in water can produce the tone, but that bats with their heads momentarily placed under water stop doing so at once.

It seems unlikely that a bat breathes in and out fifty or sixty times per second. How then does it breathe ? I think the answer is that it breathes relatively slowly, say two or three times a second, and that it phonates both during inspiration and expiration. In support of this idea the following facts may be noted. A cat can purr both during inspiration and expiration ; most men can whistle and a few men can sing and hum during both phases of respiration ; a skylark sings continuously without any detectable break, and during the whole time it must be respiring. Probably many other instances could be given. It seems likely that the bat is able to produce its supersonic tone in a similar manner.

Audio-Location and Radar

It is obvious that the basic principles of audio- and radio-location are very similar ; in both cases a beam of wave-energy is projected forward, with the object of detecting the presence and position of objects in the vicinity. In the case of the bat this beam consists of supersonic sound waves, while radar makes use of short electromagnetic waves. The frequency of the sound waves is about 0·05 megacycles per sec., that of the electromagnetic waves is about 30,000 megacycles per sec. The velocity of sound in air being $3{\cdot}4 \times 10^2$ metres per second, the wave-length of the supersonic tone is about 0·7 cm. The velocity of electromagnetic waves in air being 3×10^{10} metres per second, the wave-length of the electromagnetic wave is about 1 cm. Since, other things being equal, the resolving power is inversely proportional to the wave-length, the bat has at its disposal a potential resolving power about equal to that of radar equipment. But conditions are actually more favourable to the bat, since the bat by the employment of its two ears can use stereophonic perception.

A man in an aeroplane can determine the distance away of an object by measuring the time taken for the electromagnetic pulse sent out to return again after reflexion. This pulse has a duration of about one millionth of a second, and, as in the case of the bat, the number of pulses emitted per second is variable. In the bat they vary from 12 to 60 pulses per second ; while in the aeroplane they vary from 200 to 20,000 pulses per second. In both bat and aeroplane, the pulse frequency is raised as obstacles ahead get closer.

The bat may also determine the distance away of objects by ascertaining the time of the emitted sound after reflexion to stimulate its ears.

In the aeroplane the receiver is made insensitive during the radiation of the supersonic pulse. There are grounds for suspecting that the ears of the bat are similarly made insensitive during the radiation of the supersonic tone by a special reflex called by Galambos the intra-aural reflex.

THE CONCEPT OF MENTAL MATURITY

By PROF. A. W. WOLTERS
University of Reading

IN a recent address under this title[1], Prof. Pear has examined a much-used term. Studying a wide range of examples from modern literature, he has no difficulty in showing that it is employed in very divergent senses, none of them clearly defined. The publication of his lecture is to be welcomed, for it is a delightful addition to his book, "The Maturing Mind"[2]. It is written in the stimulating manner we expect from him, and adds to the hints given in the book as to the rich meaning which he attaches to the term 'maturity'. Above all, it challenges us to endeavour to think more clearly.

In this topic we meet a familiar stumbling-block. Scientific psychology followed upon a long period of popular thinking on psychological matters, and we have consequently inherited a number of words which, though current in general discourse, baffle us when we try to fit them into a scientific framework. We found the word 'attention', which obviously denoted some important mental processes. Years of analysis were needed to discover what they were, and now it appears that we can do without the term. 'Intelligence' has proved even more difficult. Progress would have been more rapid if psychologists had started with a clear field, unhampered by the demand to give scientific precision to non-scientific terms, or to extract clarity from concepts which had been developed for purposes other than ours. We are too socially determined to break away by a single effort. We must accept the situation, and try to bring some order into these untidy ideas. Pear has turned our attention to an important and difficult example of such problems. I would suggest that it would be premature to attempt to give a formal definition or full analysis of 'mental maturity' here and now. A piecemeal process of clearing up is more practicable. Perhaps in the end we shall find that this term is otiose.

I am encouraged to take up the author's implied challenge by his own warm-hearted defence of the second-best[2]. If we lack perfectly clear ideas, may not imperfect ones be better than none ? By scientific standards, the concept of mental maturity cannot be regarded as more than second best; but it is reasonable to suppose that people mean something when they speak of it, though they may be unable to say just what they mean, and though they may convince us that they mean quite different things at different times. Pear could easily riddle me with awkward questions if I asserted that he is mentally more mature than a child of ten, but I am sure that my statement would not be nonsense. I am convinced that I should be employing a useful concept, though I were entirely at a loss when invited to put it into consistent words. I have argued elsewhere[3] that operative concepts are not safely to be judged from their verbal expression. Ordinarily the term 'maturity' implies the application of a criterion which is not stated. It would be wrong to conclude that the criterion is absent and the concept worthless. But better things are expected of psychologists.

Maturity is a terminal point on some kind of scale The position reached by an organism at any moment is judged by the criterion provided by the limit. In the case of a single function of a simple organism, it s commonly easy to find the criterion. Thus an animal is sexually mature when it is capable of eproduction. The criterion here is the fulfilment of a fundamental biological tendency. Since our bioogical systems usually take reproduction as the most mportant single function, it is found convenient to define maturity in relation to it. But this is no final solution, since the simplest organism must have other unctions, essential as carriers of sex, which exhibit development. Nor can we regard a boy in a civilized society as mature for paternity at sixteen.

The problems we are considering become urgent as soon as we view the whole organism in its setting. Yet we can learn from the simple case where the difficulties lie. In zoology, reproduction is taken as the ardinal function. Importance is attached to it somewhat arbitrarily on the ground that the species is a more fundamental and permanent scientific object han the individual. The fuller universe is ignored. This is the ordinary scientific abstraction, necessitated and justified by our incapacity to deal with reality as a whole. Yet the individual must remain alive until it has reproduced itself, and thus requires the development of functions making for the maintenance of life. Consequently we cannot arrive at a completely adequate definition of maturity until we have analysed out all the functions considered important and decided what is the criterion of maturity of each. The more complex the pattern of the creature's life, he more difficult is it to disentangle the essential hreads.

We can, however, now state more definitely the meaning of 'maturity'. An organism is mature when each of its functions is developed to a stage which permits of the achievement of its specific end, and when all the functions are organized to co-operate in attaining that end, which we, for assignable cientific reasons, take as cardinal. It is clear that omething arbitrary remains in this definition, and qually clear, I hope, that there is no humiliation in recognizing that we may find a level of complexity such that we cannot at present make decisive statements in terms of it. We may still judge the organsm's maturity in respect of this or that function, and permit ourselves now and then to talk vaguely, but not carelessly, of full maturity.

From this point, the word 'maturity' will refer to he mental maturity of the human individual. There s no need to enlarge on the complexity of the life pattern. We do not possess a definitive list of the specific strands of activity or of their ends, and if we id we should probably be unable to work with it as coherent whole. More urgent is the question, What shall we take as the cardinal end ? Reproduction, or o know God and enjoy Him for ever ? The answer will affect our system building. But psychology is not competent to decide issues on this plane, and here may never be agreement. The quotations adduced by Pear show plainly that the various writers have been influenced by wider values than hose of empirical science, and the true outcome of is address, as of his book, is a demand for a philoophy of life. To this psychologists may properly ontribute, but they cannot undertake it solely by heir own methods. So for the present we must again fall back on second-best thinking. The individual has o react to his environment, of which we may safely take society to be psychologically the most important. Deriving our criterion from this consideration, we may say that an individual is mature if and when he successfully meets the problems set to him by the society in which he lives (if we could agree as to what constitutes success). We thus accept an ethnocentric standard. We can only judge maturity by behaviour, which does not occur *in vacuo*. It would be unreasonable to demand the capacity to complete tasks which in fact will never be set, there having been no opportunity to learn the appropriate responses. Maturity must be judged by reference to the person's social framework, and the Papuan may be as mature as the European if he discharges as competently the duties which life sets before him. An odd consequence of this argument is that maturity must be allowed to children of all ages, if they successfully meet the demands properly laid upon their age. Actually children often appear surprisingly mature, when one meets them on their own plane. They live in two societies, that of their contemporaries and that of adults. They will appear mature or immature according as we view them in one or the other context.

This criterion is easier to state than to apply in the immense complexity of civilized life. There is a present-day tendency to use the term 'culture pattern' in a free-and-easy way which masks the intricacy of the facts which it denotes. At best we have only a formal criterion, and still lack an analytic description. There will be general agreement that integration is important, and we have hopes of being able in the end to describe it in some detail. Then Pear quotes, with well-deserved approval, Allport's views on the mature personality. He summarizes them thus. "In his opinion, the mature personality should have these attributes : richness, congruence, a variety of autonomous interests, extension and objectivation of the self, a unifying philosophy of life which represents to oneself one's place in the scheme of things and gives a long-range perspective"[4]. This should induce modesty in psychologists. What must *we* be to handle all that' ? And who can be called fully mature by that standard ? Allport's statement is a limiting conception, highly valuable as such, but less useful when applied to the description of particular cases. Moreover, we can only judge maturity by overt behaviour, which is the end-product of the integrated tendencies; and the more complete the integration the less opportunity is there to judge what lies behind. In short, Allport states an ideal of development rather than a working concept, and ideals take us into other fields. And are we not tending to identify maturity with wisdom ? This may be right, but we should amend our neglect to examine the concept of wisdom before we jump to that conclusion. Prof. Pear would add to our debt if he would undertake the task. He has made a useful start by emphasizing the importance of emotional integration as well as intellectual. Then we remember those very wise and well-integrated persons of moderate intellect and restricted experience. Are they mature ? If so, what is the minimum intellectual development required for maturity ? I do not know the answer to the latter question, but I shall continue to respect the wisdom and maturity of the fisherman and the farm worker.

When we have considered the development of specific innate tendencies, their modification by environmental conditions and their systematic integration, there remains one puzzling factor to work into our scheme, and that perhaps the most distinctively human trait. It is the capacity for growth and variation. No concept of maturity can stand that does not allow for it, and yet it cuts across any tidy description of a completed personality. This may be an important source of our difficulties. We demand integration and adaptation; but an integration so complete that all responses are psychologically automatic has gone beyond maturity. The person is over-ripe. Variability must be preserved for adequate living. It is as important as intelligence or emotional development, and must somehow be integrated with them in fact and in theory. We must insist that maturity is not only compatible with, but also includes essentially an intellectual restlessness and a striving for the unattained. When the capacity for development is lost, death has set in. It would be easy to construct a plausible description of maturity which equated it with mental death. We are now on the way to answering one of Pear's questions. The truly mature personality, having retained at full strength the capacity for change and adventure, will consequently appear juvenile, and perhaps capricious. When tasks are not pressing upon him he will become sportive and (at least in the eyes of those already mentally dead) rather ridiculous.

My concept of maturity demands that the mature and wise should at times permit themselves to be silly, and those who dislike the word can look up its etymology. When I was interviewed at the outset of my university career, the principal insisted upon my joining him in shooting at a copy of *The Times* with toy bow and arrows. This was not an early example of 'selection procedures'. He just felt like that, and there were many equally surprising moments in the years that followed. Nevertheless, I rank him among the great and wise of his day. The 'sense of humour' is another facet of this trait, implying a capacity to see things in a novel light, to change relations and to respond in an unexpected way. But admittedly a capacity for the unexpected is poor material for science, and perhaps beyond assessment by exact measurement. So by this route also we only reach what Pear might call 'Tudorbethan' thinking—just better than none at all. But we are gaining control of the concepts of development of specific traits, of integration, and of variation of response. Having these, need we continue to employ a term like 'maturity', which inevitably carries an ethical and emotional tinge? We shall be well advised to use it only with the restricted connotation relevant to the immediate context. Even so, let us bear in mind Aristotle's dictum. "We must be content if we can attain to so much precision in our statement as the subject before us admits of: for the same degree of accuracy is no more to be expected in all kinds of reasoning than in all kinds of handicraft"[5]. It may be added that those who desire to study thoroughly and constructively the nature of maturity might well begin with the "Nicomachean Ethics".

Lastly, encouraged by a recent conversation with Prof. Bott, let me suggest a new turn to the discussion. We judge that a particular reaction is mature. We cannot safely judge that the personality is mature. Though the whole personality may have been brought to bear upon the act, it is not limited thereto. A human personality is extended in time as the physical organism is in space and time. One is no more present at a point in time than is the other at the intersection of certain spacial co-ordinates. It may be convenient to overlook this in rough-and-ready speech. Cross-sections and momentary aspects are indispensable means of knowledge, but they can never give full truth. "Call no man happy until he's dead" is not pessimism but sound science, for the total man has not existed until th moment. So with maturity. The term is applicab to an epoch rather than to an instant. It is a histor not a static quality. We may picture life as an asce to an undulating plateau followed by a drop to zer abrupt or gradual as fate decides. '*X* is mature' w be a true statement if the history of a substanti section of the total life of *X* shows the characte which we deem to be significant. One may occasio ally be permitted to be less austere, but we shall wa in sticky mud if we insist on applying terms appr priate to the full and continuous temporal extensi of personality as adjectives for single moments assemblies thereof. Indeed, until psychologists de far more resolutely than they have done with t temporal aspects of mental life, they must be judg to be scientifically immature.

SCIENCE IN KWEICHOW AND KUANGSI

By Dr. JOSEPH NEEDHAM, F.R.S.

British Scientific Mission in China

AFTER some lapse of time, the opportunity aga presents itself of continuing the series of articl on science in China in war-time, of which seven ha already appeared in *Nature*. In this and the followi article, on China's far south-east, I shall be describi an area which I visited in the summer of 1944, ju before the tide of war overwhelmed nearly all of wrecking many scientific installations, and forci many of the scientific workers I met to take to t roads in evacuation or to the mountains in dispers.

Taking the city of Chungking as the central poi of China, this area is China's south-eastern quart To enter it the traveller must follow the southe road from the capital, winding over half a doz passes through the protecting mountains, until reaches Kweiyang, the capital of the relatively barr and rocky province of Kweichow. A few hundr kilometres south-east of this city is Tushan, the ra head of the uncompleted Kweichow-Kuangsi railw and here he may entrain for the descent throu mountains wreathed in cloud to the fertile plains a rolling hills of Kuangsi around the city of Liuchc The capital of Kuangsi is, however, farther east, Kweilin, amidst that extraordinary scenery of 'Kar limestone pinnacles and sugar-loaf hills rising abrup out of the plain which justifies to the incredulo foreigner the fidelity of Chinese scroll-paintin Thence the railway goes on the east, bearing nor to Hêngyang and then south to the tempora railhead at Kukong in Kuangtung.

Between Chungking and Kweiyang at a small to called Tsunyi is to be found Chekiang Universi one of the best four in China. Housed largely in and dilapidated temples, there is not enough ro for all of it at Tsunyi, so the scientific faculties situated at a very pretty and very small town, Meit some 75 km. away to the east. It is typical of t present transport situation in China that althou the University started with three trucks and a to maintain its communications, all have long ago broken down and are unrepairable and unreplaceable, o that eminent and aged scholars such as the deans f faculties on their necessary journeys have to perch n the top of loaded army trucks on a trip which may take two days, over a road passing through very ew inhabited places.

The president of Chekiang University is Dr. Chu Ko-ching, China's leading meteorologist, who is concurrently head of the Academia Sinica Meteorological nstitute. At Meitan one finds a hive of scientific ctivity. The Biological Department, headed by Dr. Bei Shih-Chang, a pupil of Spemann, Harms, and Hertwig, has been working on induction phenomena in regeneration in cœlenterates, insect hormones, etc. Here also at the time of our visit was the eminent eneticist Dr. Tan Chia-Chen, whose work on the curious colour-pattern inheritance in ladybird beetles is now arousing much interest in the United States, where he has gone for a year's visit. In chemistry here are Dr. Wang Bao-Rjêng (a pupil of J. F. Thorpe's), working on sulpha-drug derivatives (some of which have been found to be active as plant-growth hormones), and Dr. Wang Chin, a specialist on microanalysis and the history of Chinese alchemy. This very active-minded group is completed by Chang Chi-Kai, a German-trained specialist on local anæsthetics, and by Sun Tsung-Pêng, American-rained biochemist.

In physics, work is proceeding mostly on theoretical ines owing to lack of apparatus, in nuclear physics, geometrical optics, etc.; but the level is distinctly high (Drs. Wang Gan-Chang, an Edinburgh man, King Hsu-Bao, Ho Tsêng-Lu, a pupil of Millikan's, and the promising Chêng Kai-Djia). There is a special mathematical institute directed by the geometer Dr. Su Bu-Chin.

The Agricultural Research Institute, with a large area of experimental plots, is also doing much work. Dr Lo Têng-Yi, in biochemistry, has discovered a ugh vitamin content in the large hips of the local wild rose *Rosa multiflora* (20 mgm. ascorbic acid per gm., and 30 mgm. vitamin P per gm.), and some 35 mgm. per gm. of vitamin P in the Chinese 'date', or 'jujube' as it should be called, *Zizyphus vulgaris*. Dr. Bai Han-Hsi, in the fermentation division, is studying the interesting Kweichow 'barm' used in making the famous 'mao-tai' wine, which, besides its yeast, contains no less than twenty-eight special added drugs, some of which accelerate saccharification while others probably inhibit contaminating micro-organisms. This recipe is an extraordinary example of a procedure with centuries of trial and error work behind it, ensuring good results under country conditions where no sterilization precautions are taken. It even has a war importance, for a certain proportion of the power alcohol used by Allied military trucks upon the roads of China is distilled from spirits prepared in the traditional way by the farmers, and brought to central distilleries. In soil science, under Dr. Pêng Chien, investigations on soil pH are in progress, and on trace elements, nickel, zinc, etc., with special reference to tea, legume, and vegetable culture.

In Tsunyi, there is also the All-China Sericultural Research Institute, where very solid work, led by Dr. Tsai Bao, goes on.

At Kweiyang, a larger town than either Tsunyi or Meitan, we found a number of scientific organizations. The largest was the Army's Emergency Medical Service Training School in a beautiful wooded valley among hills called Tuyünkuan; but besides this there were two civilian medical schools, Hsiangya Medical College and Kweiyang Medical College. There was also the Kweichow University, situated some 20 km. to the west of the town in the famous park of Huachi. There was a branch vaccine laboratory of the National Epidemics Prevention Bureau, a branch of the National Agricultural Research Bureau, a number of important industrial enterprises including a low-temperature carbonization plant and a chlorate plant, and several plants of the Ordnance Administration. About 150 km. to the west, at a pretty town called Anshun, there was the regular Army Medical College. Finally, within Kweiyang city, there was the Provincial Science Institute. Among such a wealth of worthwhile institutions, there is space to mention only a few salient points of interest.

The Tuyünkuan College was originally organized by Lieut.-General Robert Lim (Ling Ko-Hsing), the internationally known Edinburgh physiologist. It trains all grades of medical workers for the army, alternating laboratory courses with experience in the field. Dr. Chen Wên-Kuei's model vaccine plant and bacteriological laboratory deserve mention; Dr. Ling Fei-Ching is studying the penicillin production of the indigenous strains of *Penicillium*. An interesting and valuable X-ray apparatus repair station (the only one in China) is directed by her husband, Dr. Rjung Tu-Shan. In teaching chemistry, Dr. Li Kuan-Hua has organized extremely ingenious semi-micro methods which it was a pleasure to see in use by his classes. The reagent sodium tungstate was being manufactured here. The Hsiangya Medical College (Dean Chang Hsiao-Chien, a pupil of Krogh's) had some wretched buildings; but excellent men, such as Dr. Chêng Wên-sse the pharmacologist, studying the Chinese drug 'Yadantze' which has an emetine-like action in dysentery. The Kweiyang Medical College (President Li Tsung-Ên, trained at Glasgow) has the distinguished pathologist Dr. Li Yi, and among her colleagues the American-trained embryologist Dr. Chang Tso-Gan. The psychiatrist Ling Ming-Yo represents a field hitherto little cultivated in China. Both these medical colleges were running up-to-date teaching hospitals.

Two of Zinsser's pupils in Kweiyang, Dr. Wei Hsi, of the National Epidemics Prevention Bureau branch laboratory, and Dr. Liu Pin-Yang of Hsiangya, were engaged upon a very interesting project, namely, the cultivation of typhus Rickettsia bodies in the cœlomic fluid of silkworm larvæ and pupæ (in which good growth is obtained) instead of the yolk-sac of the chick embryo. If this method could be used successfully, it would greatly simplify the preparation of the Cox vaccine under Chinese conditions, where incubators are not available but silkworms are.

The regular Army Medical College at Anshun (director, Lieut.-General Chang Chien) is located outside the town on an airy moorland in a spacious old Ching dynasty barracks, with the various institutes scattered around in scenery like that of the Scottish Highlands. The most important institutes are those of bacteriology, directed by Major-General Li Chen-Pin, and of nutritional science, under Dr. Wan Hsing. Li Chen-Pin, when at the Rockefeller Institute in younger days, carried out classical work with T. M. Rivers. Rivers and Goodpasture were the first to cultivate viruses on the chorio-allantoic membrane of the chick embryo; Rivers and Li were the first to cultivate them (vaccinia and yellow fever) on explanted fibroblasts. Yellow fever vaccine is still prepared in this way. Unfortunately, lack of equipment prevents much research in these institutes, though manufacture of vaccine goes on. The pharmaceutical institute maintains a model factory in which there is a certain production of drugs, and there is a good pharmaceutical garden and farm under Dr. Kuan Kuang-Ti. The Army is planting in Szechuan hundreds of thousands of saplings of the tree *Dichroa febrifuga*, from which is derived the drug 'changshan', known in the Chinese pharmacopœia at least as far back as the Sung dynasty, and recently found in both London and Chicago to have a parasitocidal action in animal malaria.

One of the best types of institution in the Chinese development of the sciences has been the provincial science institute. Reference has already been made to certain of these seen in other provinces; but the one at Kweiyang, directed by Dr. Ling Shao-Wên from the Emergency Medical Service Training School, was extremely good. For popular education there were really good exhibits of parasitology, highway engineering, war gases, embryology (including man), geology and mineralogy, and nutrition. A splendid room, prepared by Mr. Liu Ting-Wei, a great authority on the subject, demonstrated the life-cycle of the Kweichow wax-insects, allied to aphids. This indigenous industry gives a large annual production of highest-quality wax, and both the insect life-cycle and the industrial methods are very curious. The Provincial Science Institute also manufactured scientific apparatus for schools, and had been planned with spacious centralized laboratories for school practical work; but in war-time it had proved impossible to equip them.

If the exhibitions at the Kweiyang Science Institute were the best I had seen, the apparatus manufactured at the Kuangsi Science Institute was the best of its kind. A good many reading machines, for use with the microfilmed journals sent out by the British Council and the State Department of the United States, have been made here. The Institute, which had an excellent building, adjoined those of Kuangsi University (president, Li Yün-Hua, a chemical engineer) around a sloping patch of grass in the hills, rather resembling an English village green, at Liangfêng, some 25 km. south of Kweilin. Near by, among groves of pine trees, were the wooden buildings of the Academia Sinica Institutes of Geology (under the internationally known Dr. Li Se-Kuang (J. S. Lee), of Physics (under Dr. Ting Hsi-Ling), and of Psychology (under Dr. Tang Yueh).

When I was there, Dr. Li was particularly interested in the distortions produced in stone under glaciation, analogous to the 'bending' of tombstones, etc. Work was proceeding on palæobotany (Sse Hsing-Chien), ***Kleintektonik*** (Chang Shou-Chang), and mineral ore structure (Wang Yin-Chih). Associated with Dr. Ting was Dr. Parker Chen (Chen Tsung-Chi), the well-known former colleague of Sven Hedin. Away in the hills a very fine terrestrial magnetism station was working; located in a specially built non-magnetic and thermostatic house, it took continuous photographic recordings of all three elements, and possessed excellent apparatus, some of it made in the Institute's own workshops. The smallest of the three Institutes was that of Psychology (really developmental physiology of the nervous system); Dr. Tang was carrying out transplantations on the beautiful transparent tadpoles of *Microhyla ornata*. There was a particularly good library of neurology and experimental morphology, housed in a separate building.

Probably the best scientific department of Kuangs University was that of chemistry. Here Dr. Amo Pêng (Pêng Kuang-Chin) was working hard with hi group on the indigenous plants which contain rubbe in their sap. Several useful new sources in Kuangs have been found, notably the climbing fig *Ficu pumila* and the giant vine *Chonomorpha macrophylla* Many experimental articles have been made from these rubbers.

The other most outstanding scientific institution in Kuangsi province was probably the Ministry o Agriculture's Experiment Station at Shatang, near Liuchow, covering 7,000 acres and comprising many good laboratories. Directed by Dr. Ma Bao-Chih, the translator of 'Sturtevant and Beadle' and other important books, it was a scene of great activity Choosing at random from among the divisions, Dr Huang Liang (economic entomology) demonstrated the bamboo comb designed for use by the farmers to get the caterpillars of the rice skipper, *Parnara guttata*, off the rice plants, and the box coated inside with a sticky mixture of pine resin and teaseed oil, for getting the flea beetle, *Phyllotreta vittata*, off the cabbages. Dr. Chang Hsin-Chêng (a pupil of Waksman) demonstrated the production of inoculum of root-nodule bacteria. Particular attention was being paid to sugar-cane improvement, tung-oil tree (*Aleurites fordii*) culture, rice selection, and storage of citrus fruits. Dr. Huang Rjui-Lun had shown that during the storage of the pomelo or 'yudze', the ascorbic acid content actually rises, up to a maximum. Attention was being paid to naturally occurring insecticides.

Circumstances have forced me to make considerable use of the past tense in this article. It will be remembered that in last year's campaign, the Japanese, starting from Changsha as a focus on the southern edge of the Japanese-held north-east quarter of China, pushed down to Hêngyang, cutting off the far south-eastern provinces, and then successively down to Kweilin, Liuchow, and Nanning, thus acquiring a corridor with Indo-China. From Liuchow they pushed up the railway to railhead at Tushan and a little beyond, but stopped at the frontier of Kweichow, not however without having caused a partial evacuation of Kweiyang. What happened to the scientific workers?

It is sad to have to record that the Liangfêng centre was practically destroyed. The Academia Sinica Institutes evacuated their personnel to Chungking, but lost a great deal of apparatus which could ill be spared. The Library of the Institute of Psychology was almost completely lost. Kuangsi University personnel were evacuated into the mountains west of Liuchow and have not been heard of since. Both the Provincial Science Institutes were ruined, that at Liangfêng by the Japanese, and that at Kweiyang, with its laboriously arranged exhibitions, by having Chinese troops quartered in it and being "put in a posture of defence". The Shatang agricultural station was overrun; but it is believed that the records were evacuated in time. It is to be feared that some scientific workers and their families were caught in the congested refugee areas at railhead, where the mortality was appalling. I myself met Mrs. Chou, the wife of the Fukienese physicist Chou Chang-Ning (a Cavendish man), on the station platform at Liuchow just before the fall of Kweilin, and did what I could to assist the onward journey of her and her children. Fortunately, Tsunyi, Meitan, and Anshun were not affected; but Kweichow University was, the students and professors simply setting out to walk, carrying what books and apparatus they could, as if it were a thousand years ago. This University has now re-assembled at Huachi. Hsiangya and Kweiyang Medical Colleges, however, managed to secure some truck transport and moved to Chungking, where they are remaining for the time being.

Western Kuangsi was recaptured early this year from the Japanese, but in a ravaged state. The city of Liuchow, for example, was burnt to the ground. The scientific development of these provinces was just in its opening phase, stimulated by the evacuation from the coastal cities; it has been distressing to see so cruel a frost nip it in the bud.

OBITUARIES

Sir David Milne-Watson, Bt.

A LEADING national industry and a wide circle of friends and admirers will regret the death on October 3 of David Milne-Watson. He was one of those Scotsmen possessed of unbounded energy and enormous capacity for work who, trained as a lawyer, developed great administrative and organizing ability coupled with a facility to understand human nature which made him a great leader of men of all grades of society.

Born in Edinburgh in 1869, he gained two degrees at the University before entering a law office. Something lured him to Balliol College, Oxford, and from there he completed his education at Marburg. He was tempted by politics like many young lawyers of his time and contested the South-Eastern Division of Essex in 1895. Fortunately for the gas industry he was unsuccessful, and though he was called to the Bar in the next year we find him attracted into industry in 1897.

A large statutory company like the Gas Light and Coke controlled by various Acts of Parliament has need from day to day of the best legal assistance: the Company chose Milne-Watson for this work. Once there his administrative abilities developed rapidly; he became general manager in 1903 and managing director in 1916. Two years later he became governor, a position giving him the supreme leadership of the Company. He held this post until April last—a term of forty-eight years with the Company.

This is not the place to trace the development of the Gas Light and Coke Co. under his leadership. It provides a highly efficient service for Greater London north of the river; indeed it stretches from Windsor to the North Sea, and is both the largest and the leading gas company throughout the world.

Milne-Watson became a technician as well as administrator; he appreciated to the full the part that science should play in the gas industry and provided full opportunity both for research and development. He was responsible for the installation of adequately equipped and staffed research laboratories to deal with gas manufacture, tar products and the utilization of gas.

Milne-Watson had the inspiration at an early stage to enlist the co-operation of Sir Harold Hartley, and the edifice created between them has placed the gas industry in the forefront of those industries which by research work in all the sciences are continually giving better service to the public. So far from being effete, as is sometimes suggested, the gas industry is in the very forefront of progress, an achievement which redounds very largely to the credit of Milne-Watson.

Milne-Watson realized also the responsibility which lies on a large firm to promote the education of its employees. Every encouragement and special facilities for study were provided, while Milne-Watson himself served on several important committees dealing with education. As the leader of the gas industry in Britain he could not escape a large share of the co-operative work required by the industry, including the relations with labour; and here again his high qualifications made him a member of many national labour inquiries, committees and conferences, including the International Labour Office at Geneva. Space prevents reference to his many other activities, for he was unsparing of his energies in helping national and public causes.

But it is essential to stress his human qualities. He had the widest possible circle of business friends, to whom he was never too busy to give a word of kindly advice or lend a helping hand. In his own Company he prided himself on being the 'father' of a great family. Though forthright in utterance, he was a very lovable and much respected man. He became a knight in 1927 and a baronet in 1937, and had two sons and a daughter.

E. F. ARMSTRONG.

Dr. A. Lees

DR. ANDREW LEES, of the Projectile Development Establishment (Ministry of Supply) and University College, Swansea, died suddenly, after only a few days illness, on August 29, in his thirty-fourth year.

Dr. Lees was born on November 30, 1911. He had a brilliant career at University College, Nottingham, taking the B.Sc. with first-class honours in mathematics, winning the Lubbock Prize awarded by the University of London, and then taking the M.Sc. with a mark of distinction. His research work in quantum mechanics gained him a scholarship at Trinity College, Cambridge, where he studied under Prof. P. A. M. Dirac, who described him as possessing a quite unusual imagination and power of abstraction. Dr. Lees obtained the Cambridge Ph.D. degree, and was then appointed to the staff of University College, Swansea, but he had only been there about two years when war broke out.

After a short period in the Army, Dr. Lees was transferred to the Projectile Development Establishment at Cardigan. Owing to the requirements of official secrecy, details of his work there cannot be given; but it is allowable to say that as a member of the ballistics group he made several valuable contributions to the theoretical and practical aspects of the external ballistics and fire control of anti-aircraft and other weapons. In his spare time he continued his researches in quantum mechanics and related branches of mathematical physics; at the time of his death he had two papers accepted for publication and he was engaged on a third. His correspondence shows that he had many ideas which he was hoping to develop as soon as he could be released from war duties, and his published work would, in all probability, have been considerably augmented if he had been spared for even a few more years.

We extend our deepest sympathy to his widow and two young daughters.

H. T. H. PIAGGIO.

NEWS and VIEWS

Prof. F. E. Weiss, F.R.S.

On November 2, Prof. F. E. Weiss will be guest of honour at a meeting attended by botanists and other men of science in the rooms of the Linnean Society of London to celebrate his eightieth birthday. It is doubtful whether any other man of science in Britain has exerted a greater influence over botanical research and teaching for so long a period as Prof. Weiss has; many botanists and other men of science owe much to his sympathetic guidance and encouragement in their formative years, and, with this in view, the Editors of *Nature* wish to add their contribution to the many messages of esteem which will assuredly greet him on this occasion, for Prof. Weiss has been a contributor to *Nature* over a very long period. But it was at Manchester where Prof. Weiss's main work was carried out: he was George Harrison professor of botany in the University there for thirty-eight years. We cannot do better than quote from the resolution adopted by the University Council on the occasion of his resignation from the chair in 1930: "During his tenure of the Chair he has built up a great School of Botany, which bears a distinguished name both at home and abroad. It is renowned for the researches which have been carried out by the members of the School and for the unusually large number of men and women it has trained who now occupy positions of influence in many spheres of botanical work." At Manchester, Prof. Weiss was also closely concerned with the development of the University itself, especially during 1913–15 when he was vice-chancellor.

On his resignation, Prof. Weiss moved to the south of England—not to rest, but to carry on much useful work with that zeal and understanding which always characterized his work at Manchester. The Linnean Society itself owes much to him—he was president during 1931–34. He has also influenced practical horticulture—he always has been a keen gardener—through his membership of the Council of the Royal Horticultural Society. The British Association owes much to the wise counsel and mature judgment of Prof. Weiss, especially since his release from academic duties at Manchester gave him more time to work for the advancement of science in general. He was joint honorary secretary of the important Committee on Post-War University Education which was constituted by the Association and which issued its report in 1944. It is doubtful if a man of Prof. Weiss's active and alert nature would ever consider resting in spite of a personal history of work for cultural advancement of which any man could be proud; we wish, therefore, to extend our congratulations to him on this occasion, and hope that science and education in general and botany in particular may long continue to have the advantage of his stimulating influence.

Institute of Agricultural Economics, Oxford: Retirement of Dr. C. S. Orwin

Agricultural experts throughout Britain, and indeed over a wider area, will learn with regret that Dr. C. S. Orwin is due to retire at the end of this year from the Institute of Agricultural Economics at Oxford. He was its first director, and from the outset he started it on lines which have since proved very fruitful. He adopted the method of getting right down to the working details of farming by keeping farmers' account books and working out costs of different operations under different conditions, and he published detailed descriptions of the methods of some of the more outstanding farms, especially where new lines have been struck out. In addition, he published an interesting account of the working of the old three-field system, and also of the reclamation of Exmoor. More recently he has devoted his attention to the replanning of British agriculture and village life, and has made some very thoughtful contributions to this important subject. His recent survey of a section of Oxfordshire is a brilliant example of this type of work. In these social and historical investigations he has been ably assisted by his wife, who is herself an expert on these subjects. Not the least of his services has been the training of a staff, some of the members of which have since rendered distinguished service in other institutions. His many friends will wish him long, pleasant and active years of retirement.

Agricultural Engineering Record

The contents of the first number of *Agricultural Engineering Record* provide a good example of the intended scope of this publication, the main purpose of which is to place on record the results of the testing, experimental and research work of the National Institute for Agricultural Engineering, Askham Bryan, York (London: H.M. Stationery Office. Pp. 32. 1*s*.). The subject selected for special review is segmented sugar-beet seed. This process, which originated in the United States, breaks up the seed clusters before sowing by means of a machine, thereby facilitating singling later. Tests carried out on large-scale observation plots in England are described, from which it appears that there was no difference in the yields of beet grown from segmented and natural seed. Another article gives the results of measurements of grain losses with the combine harvester, showing that such losses can easily be of an order which makes the process uneconomical; and it is suggested that attention be paid to improvements in the general design of the cutter-bar, as it is here that the greatest source of loss occurs. Comparative tests with three machines used in sugar-beet harvesting indicated that each was superior to the others in at least one respect, and work is in progress on the production of a composite machine. Grain bin ventilation, a grain flow meter, a coulter for ploughing-in straw and an offset potato-digger form the subjects of the shorter articles, and the number concludes with what is intended to be the chief feature of the publication, namely, summaries of the National Institute's test reports of implements or machines specially imported for research purposes, or experimental prototypes not yet in production.

National Research Council (Canada): Post-War Planning

The twenty-seventh annual report of the National Research Council (Canada), for 1943–44, includes the report of the acting president, Dr. C. J. McKenzie, the financial statement for the year ended March 31, 1944, and reports from the directors of the several divisions, amplifying the information contained in the preliminary review of the work of the Council already issued (see *Nature*, 155, 737; 1945). Referring to the broader aspects of post-war planning for scientific research, Dr. McKenzie's report states that in a brief review of research programmes in Canada, Great Britain, United States and the U.S.S R. it was observed that Canada had hitherto been largely a research importer, and that the Dominion's pre-war *per capita* expenditure of research was far below that of other industrial nations. It is suggested that Canada, through its National Research Council, should maintain in the immediate post-war years a programme of research equal to, or greater than, the present war research effort, which is five times as great as that of the pre-war years. Consideration has been given to a long list of topics suggested as subjects for research in the post-war period, and suitable action indicated. Among many new problems suggested to develop the natural resources of the Dominion or to improve living conditions of the people may be mentioned road research, housing and building research, transport by air, rail, road and water, cold weather and northern latitude problems and the utilization of agricultural crops and products of the forest. Research is recommended on the construction, heating, lighting etc., of small homes, the development of cheap refrigeration units for farm homes, cold-storage locker systems for farms, and farm equipment including plumbing and farm-power units.

It is recognized that the universities must remain the chief centres for training scientific personnel in special fields and should be the chief centres for pure research, although such research must be fostered to a limited extent in the Council's own laboratories. The chief concern of these laboratories should be research on problems expected to yield results for immediate practical application, and provision should be made for this work to be carried to the stage of pilot-plant operation. Provision for the interchange of research workers between the National Research Council, universities, Government departments, and other research organizations in Canada is strongly recommended, as well as the development of research intelligence and the international exchange of research information. The establishment of liaison officers in London and Washington is noted as a policy which might be profitably extended in the post-war period. The value of such co-operation in war research is specially stressed in this report, which notes that it has been possible to plan research with some understanding of the use likely to be made of the results by the Allied Nations, and also it has enabled Canadian workers to discuss their problems at first hand and to establish close relations with other scientific workers investigating similar problems.

New Map of the Moon

MR. H. PERCY WILKINS is a well-known observer of lunar features and has done a considerable amount of very useful work in this particular branch of astronomy. In 1932 he published his 200 in. map of the moon, and now he has brought out a new map which is 25 ft. in diameter and by far the largest map of the moon in existence. It is contained in 107 sheets, each 22 in. by 30 in., bound in three volumes and deposited in the Library of the British Astronomical Association, Burlington House, Piccadilly, London. This map was commenced in 1932 and displays a great amount of care and attention to details—the number of ring-like objects is about 60,000, and many other objects are noted. The number of named objects is 700, including 28 new names; all the names contained in "Who's Who in the Moon" have been included. A large number of new clefts have been inserted as a result of the author's own observations since 1932. Although positions are mainly based on Saundor's list, Mr. Wilkins has made many new measurements with a micrometer, especially of objects near the limb. The large scale—300 in. diameter—is just sufficient to show clearly minute details in the more crowded regions. It is proposed to publish the map on the reduced scale of 100 in. to the moon's diameter, in 25 sections, each 20 in. square, and for the purpose of this reproduction the entire map was re-drawn to this scale, one-third of the diameter of the original sheets. Selenographers will find this map of the moon invaluable for their work.

Trapping Fleas

A. H. AL-HUSSAINI, of the Department of Zoology, Farouk I University, Alexandria, has described, in a communication to the Editors, a simple trap for catching fleas. A plate of 7–8 mm. depth and not less than 20 cm. diameter is filled with soapy water; a one candle-power petroleum lamp, with a flat supporting base, is put in the middle of the plate. Fleas being thermotropic and thus attracted by the heat of the lamp, they jump towards it and fall into the plate, where they are rapidly 'drowned' in the soapy water. The great majority of fleas caught by this trap are females. Two possible interpretations to this high percentage of females can be offered: (1) the female seeks a hide to lay its eggs, and the hotter the hide the more favourable it is for hatching the eggs; (2) the numbers may indicate the natural ratio between the females and males in the human flea (*Pulex irritans*), which would thus be approximately 25 : 1.

The Venereal Diseases

A RECENT pamphlet, "People Who Live in Glass Houses", by a "V.D. Orderly" (Harold Thomas) (London: The Central Council for Health Education, 1945. Pp. 80. 9*d*.), gives an accurate account of the common venereal diseases. One would guess that the material was originally used by the author for lectures to young men. As such, and delivered in a breezy 'man to man' style, it was no doubt successful with a certain type of audience; but Mr. Thomas has not achieved the task of translating his message into writing. The lay reader, who is able to accept the style, may not be inspired by the length. There is just too much to be read at a sitting and some of the information, good though it is, is redundant. An orderly in a venereal diseases clinic has a position of great responsibility and is often the friend and counsellor of the patients. Mr. Thomas has obviously made the most of his opportunities for observation of the conduct and mode of life of his patients. We can praise his sincerity and intentions but not his book.

University of Leeds

AT a meeting of the Council of the University of Leeds on October 17, Dr. W. T. Astbury, reader in textile physics in the University, was appointed to the newly instituted chair of biomolecular structure which has been established for Dr. Astbury personally as a tribute to his merit as an investigator. The title of emeritus professor was conferred upon Dr R. W. Whytlaw-Gray, who recently retired from the chair of chemistry. Mr. Wilfred Prest, acting professor in the University of Melbourne, was appointed visiting lecturer in the Department of Economics and Commerce during the second and third terms of the present session.

The Council announced that the following grants to the University had been made: (1) £10,000 over a period of ten years by the Nuffield Trust to establish a readership or senior lectureship in the Dental School for the purpose of encouraging research into problems of dental health. (2) An annual grant of £600 for seven years from Messrs. Turner and Newall for the institution of a research fellowship to promote research in engineering, chemistry, physics, textile industries or any allied science approved by the donors. (3) £1,500 a year for two years from the Bradford Dyers' Association, Ltd., for the institution of two research fellowships: one in dyeing in the Department of Colour Chemistry and Dyeing; and one in Textile Finishing in the Department of Textile Industries; together with a grant of £400 to each of the two Departments for the maintenance and replenishment of their resources; (4) £300 a year from the International Wool Secretariat for the establishment of a Wool Research Scholarship. (5) 6,500 dollars from the Rockefeller Foundation for the purchase of equipment in the United States required in connexion with Prof. Astbury's researches on the analysis of biological tissues, in support of which the Foundation has made a grant of £2,140 a year during the past twelve years. (6) An annual grant of £100 from Williams (Hounslow), Ltd., for equipment for the proposed new lectureship on lakes and pigments in the Colour Chemistry and Dyeing Department. (7) £750 from Messrs. Babcock and Wilcox, Ltd., for equipment to be used in the Coal Gas and Fuel Industries Department in the training of fuel technologists.

German University in Prague

It is announced by *The Times* correspondent in Prague that, by a presidential decree dated October 18, the German University in Prague and the German technical colleges at Prague and Brno will cease to exist on November 17, the day on which the country commemorates the shooting of Czech students and the closing of Czechoslovak universities by the Germans in 1939.

Ministry of Labour and National Service: Technical and Scientific Register

Demobilized men and returned prisoners of war who are scientific workers, professional engineers, architects or surveyors, are invited by the Ministry of Labour and National Service to make use of the service provided by the Technical and Scientific Register of the Appointments Department of the Ministry, at York House, Kingsway, London, W.C.2 (Telephone: Temple Bar 8020). A technical staff, competent to give advice and assistance, has been augmented to meet problems of settlement and reconstruction. A large variety of vacancies, both at home and overseas, is now available for fully qualified men of science, engineers, etc. Inquirers are particularly asked to write or telephone for appointments, stating occupation, qualifications, and the purpose of the proposed visit.

Fiftieth Anniversary of the Discovery of X-Rays

To commemorate the discovery by Röntgen of X-rays on November 8, 1895, a series of meetings has been planned by the Royal Society, Royal Society of Medicine, Royal Photographic Society, Physical Society, Institute of Physics, Institution of Electrical Engineers, British Institute of Radiology, and Society of Radiographers acting together. On November 8, inaugural meetings will be held at the Royal Society and the Royal Society of Medicine, at which Sir Henry Dale and Lord Horder respectively will preside. During the morning of November 9 papers on "Applications of X-Rays to Physics and Chemistry" will be read at the Royal Institution, and there will be a meeting at the Royal Society of Medicine for lectures on "Diagnostic Radiology" and "Radio-Therapy". During the afternoon, at the Central Hall, Westminster, a joint meeting of the participating societies will be held at which Sir Lawrence Bragg will speak on "The Scientific Consequences of Röntgen's Discovery of X-Rays". During the morning of November 10, papers will be read at the Royal Institution on "Applications of X-Rays to Physics and Chemistry". The remainder of the day will be occupied with meetings at the Institution of Electrical Engineers: the Society of Radiographers will hold a medical meeting, and later there will be two general sessions to hear historical reviews covering X-ray equipment, X-ray photographic materials and industrial X-ray analysis.

The Night Sky in November

New moon occurs on Nov. 4d. 23h. 11m. U.T., and full moon on Nov. 19d. 15h. 13m. The following conjunctions with the moon take place: Nov. 2d. 12h., Jupiter 4° S.; Nov. 2d. 20h., Venus 4° S.; Nov. 6d. 17h., Mercury 5° S.; Nov. 23d. 13h., Saturn 2° S.; Nov. 24d. 03h., Mars 0·6° S.; Nov. 30d. 05h., Jupiter 4° S. Occultations of stars not fainter than magnitude 6 are as follows: Nov. 15d. 19h. 33·9m., 24 B. Ceti (*D*); Nov. 21d. 22h. 05·7m., 3 Gemi. *m* (*R*); Nov: 22d. 5h. 53·5m., 36 B. Gemi. (*R*); Nov. 28d. 1h. 58·3 m., ν Virg. (*R*); *D* and *R* refer to disappearance and reappearance, respectively, and the times refer to Greenwich. Mercury is unfavourably placed for observation, setting about half an hour after the sun during the month. Venus is conspicuous as a morning star, rising at 4h. 44m., 5h. 30m. and 6h. 19m. at the beginning, middle and end of the month, respectively. Mars, in the constellation of Cancer, can be seen in the late evening hours, rising at 21h. 13m., and 19h. 49m. at the beginning and end of the month. Jupiter, in the constellation of Virgo, is visible in the morning hours. The planet rises at 4h. 37m. on Nov. 1 and at 3h. 14m. on Nov. 30. Saturn, in the constellation of Gemini, rises about the same time as Mars at the beginning of the month and at 19h. 16m. at the end of the month. The planet is stationary on Nov. 6. The Leonid meteors are due on Nov. 13–14 and the Andromedids about Nov. 20–27, but both these showers have been very feeble, or in some cases practically non-existent, for a number of years.

Announcements

Sir John Boyd Orr, M.P., has been elected rector of the University of Glasgow.

Captain Arthur Dyce Duckworth, R.N., has been appointed secretary of the Institution of Naval Architects in succession to the late Mr. G. V. Boys, and will shortly take up his duties at the Institution.

The Conference in Prague on the use of X-ray methods in the metal industry (see *Nature* of October 20, p. 473) has been postponed and will take place during November 28–December 1.

Electrical Resistance of Liquid Metals

THE electrical resistance of a metal arises from the scattering of the electron waves passing through it. The fraction of these electron waves scattered in ll directions in a unit volume, which will be called the attenuation coefficient, μ, is equal to the reciprocal f the mean free path of the electrons. From this he specific resistance ρ can be calculated from the ormula

$$\rho = \frac{h}{n\nu e^2\lambda} \cdot \mu, \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where ν is the number of atoms per unit volume, n is he number of conduction electrons per atom, and is the wave-length corresponding to the Fermi urface.

In the alkali metals in the solid state, this wave-length is 14 per cent greater than the wave-length hat will give the first Bragg reflexion in the backward direction. In a recent paper[1], we have shown that this magnitude for λ is sufficient to make the scattering coefficient *even in the backward direction* conform to the Einstein-Smoluchowski formula

$$\left.\begin{aligned} E_\varphi &= \varepsilon \, . \, \nu\sigma_\varphi, \\ \varepsilon &= \nu kT\beta \end{aligned}\right\} \quad . \quad . \quad . \quad (2)$$

where E_φ is the scattering coefficient in any direction making an angle φ with the direction of motion of the electrons, defined for unit volume and for unit solid angle; β is the isothermal compressibility, and σ_φ is the scattering coefficient for a single isolated atom. (σ_φ will be proportional to the square of the atomic structure factor as usually defined.) T is taken to be sufficiently large in comparison with the Debye temperature for the thermal energy to be regarded as proportional to kT.

The attenuation coefficient will then be given by

$$\mu = \int_0^\pi E_\varphi \, . \, 2\pi \sin\varphi d\varphi \quad . \quad . \quad . \quad . \quad (3)$$

$$= \quad \varepsilon \, . \, \nu\sigma, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

where $\sigma = \int_0^\pi \sigma_\varphi \, . \, 2\pi \sin\varphi d\varphi$ is the cross-section of the atom for scattering in all directions.

In the alkali metals in the liquid state also, λ is about 13 per cent longer than λ_0, where λ_0 is the wave-length for which the first diffraction maximum is in the backward direction, $\varphi = \pi$. Though the diffraction halo of the liquid is much more diffuse than the Bragg reflexions in the solid, the above magnitude of λ is still sufficient to exclude all the intense parts of the halo. A portion of its long tail, however, extends into the observable range, $\varphi < \pi$. This forms an excess scattering in the neighbourhood of the backward direction over that given by (2), and hence μ will be in excess of the value determined by (4) by a corresponding amount. On calculation, this extra scattering in the liquid is found to account for the observed increase in resistance of about 50 per cent of the alkali metals on melting. (The increase due to changes in β and ν on melting is relatively small, about 10 per cent.)

Since the method adopted for this calculation is general, and is applicable to polyvalent liquid metals also, we will briefly describe the method here. Denoting by x_φ and s_φ the quantities in X-ray scattering analogous to E_φ and σ_φ respectively in electron scattering, we have

$$\frac{x_\varphi}{\nu s_\varphi} = \frac{E_\varphi}{\nu\sigma_\varphi}, = R_\varphi \text{ say.} \quad . \quad . \quad . \quad (5)$$

Now x_φ, s_φ and R_φ involve φ and λ through $\sin \frac{1}{2}\varphi/\lambda$ alone. Hence knowing the intensity distribution in X-ray scattering by the liquid metal, and the X-ray atomic structure factor, for any convenient wave-lengths, we know R_φ. The Fermi electronic wave-length for the metal is also easily calculated; for this purpose we regard *all* the valency electrons as conduction electrons. If now the atomic structure factor for the scattering of electron waves of this particular wave-length is known, the electronic scattering coefficient E_φ for the metal in different directions can be calculated, and thence, using relations (3) and (1) respectively, the attenuation coefficient μ and the specific resistance ρ can be calculated.

We have calculated the electrical resistances of some typical liquid metals by this method, using the known distribution of intensity in the X-ray diffraction pattern of the liquid[2] and the known X-ray atomic structure factors. Data for atomic structure factors for electron scattering for such low-velocity electrons as are involved in conduction are available for the rare gas atoms only[3], and they have been adopted roughly as the appropriate values for the corresponding alkali atoms in the metal. For other atoms, for want of similar data, the electronic scattering coefficient of the atom σ_φ is assumed to be the same in different directions, and equal to $\sigma/(4\pi)$.

Now plotting R_φ against $\sin \frac{1}{2}\varphi/\lambda = \xi$, say, it is found that in all liquid metals there is one prominent maximum for R_φ, the value of this maximum being about 2 or 3. When ξ is increased further, R_φ falls below unity, and after two or three oscillations about the value $R_\varphi = 1$, with progressively diminishing amplitudes, settles down at this value. As we proceed from the prominent maximum to smaller values of ξ, in most liquids R_φ falls quickly to a very low value, which according to the theory must be the Einstein-Smoluchowski value $R_\varphi = \varepsilon \ll 1$, and must remain so at all smaller values of ξ. In a few liquids, for example, zinc and aluminium, R_φ passes through a subsidiary maximum, before falling to ε.

Now the attenuation coefficient, and hence the resistance, of a given liquid metal will depend on how much of the diffraction pattern, the intensity of which is highly concentrated in the neighbourhood of the prominent halo, is included in the range $0 < \varphi < \pi$, or $0 < \xi < 1/\lambda$, where λ is the Fermi wave-length of the metal. In monovalent metals this range includes little beyond the Einstein-Smoluchowski region; whereas in the other extreme case when the valency is sufficiently high ($n = 5$ or 4), it includes the whole of the diffraction pattern where R_φ deviates significantly from unity. For intermediate valencies ($n = 2$ or 3), the region includes the major portion of the prominent halo, but not the whole of it.

We may mention here one striking result to which we are led by these considerations. Whereas in monovalent liquid metals the attenuation coefficient is of the order of the Einstein-Smoluchowski value, namely, $\mu = \varepsilon \times \nu\sigma$, in polyvalent liquid metals it approximates to what may be called the Rayleigh value, namely, $\mu = \nu\sigma$, which is much larger. The experimental values for the electrical resistances of liquid alkali and noble metals verify the former value, and those for liquid bismuth, lead and tin the latter, with reasonable values for σ.

The exceptional electric behaviour of mercury is due to the following circumstance. Its prominent diffraction halo, which is very sharp, is much closer to the centre than in other liquids; the spherical zone in phase space the boundary of which corresponds to this maximum can accommodate only 0·9 electrons per atom, whereas in the other liquid metals studied this number varies from 1·2 to 1·7 per atom.

Stability of the Earth's Atmospheric Oxygen

AMONG the many ways in which it is scientifically prophesied that the world, as we know it, must come to an end, there is a double 'threat' to the oxygen of the air.

It has been argued (by Goldschmidt originally), and generally accepted, that this oxygen is already much, perhaps a half part, absorbed by iron and ferrous minerals, and must all disappear in the course of time. But those who suggest this neglect the somewhat obvious circumstance that the same gravitational differentiation which separated oxygen from the iron core originally is still in operation, although now as a very slow 'geological' effect; and that, correspondingly, ferric oxide must be dissociated at a certain depth (*c.* 850 miles) provided that oxygen can escape more easily than iron through the molten basalt (as is certain).

Thus, the equivalent volumes of Fe_2O_3 and Fe_2 are 30·5 and 14·3 c.c.; the difference being 16·2 c.c., or at the pressure considered more like 14·6 c.c.; and the heat of formation of Fe_2O_3 (known at 400° C. and not likely to be greatly different, even at 4,000° C., from the specific heat trends, but possibly some 20–60 per cent *less*) is 196,000 cal. ($= 8{\cdot}23 \times 10^{12}$ ergs): from this the dissociation pressure is $8{\cdot}23 \times 10^{12} \div 14{\cdot}6$ dynes cm.$^{-2}$. Now, down to the depth considered, the changes in gravity (some 10 per cent) and magma density are not great and tend to cancel one another; so that, for a surface basalt density of 3·3, the ratio

$$\frac{8{\cdot}23 \times 10^{12}}{14{\cdot}6 \times 3{\cdot}3 \times 981} \rightarrow 1{,}372 \text{ km., or 857 miles, gives a}$$

satisfactory estimate. It is very good confirmation of this that a heavier silicate-iron layer has been much supposed to begin at a depth of 1,350 km.

The ruddy aspect of Mars has been cited as evidence of advanced formation of ferric oxide; but appropriate calculation shows that the pressure even at the centre of Mars is considerably less than that required for the dissociation—so that the cases are not analogous.

The other 'bogey' in this matter, though a slender one in its rate of action, is accredited equally or more definitely. It is argued that oxygen escapes kineti ally from the 'top' of the atmosphere, at a rat according to Maxwell's distribution law, of son $10^{-\text{hundreds}}$ gm. sec.$^{-1}$. This is no doubt the case; bu what seems to be neglected is that much more oxyge is indrawn gravitationally. Even granting the latt at present, the 'escapists' would argue that it mu escape somehow some time into 'infinite space'.

Now infinite space without a corresponding exte sion of matter is an archaic notion no longer accredite philosophically, or substantiated by observation (far as it goes); and the gravitational oxygen intal is approximately $\pi\left(\frac{\gamma m}{v^2}\right)^2 \cdot v \cdot \rho_{O_2}$ (assuming the ca ture radius $\frac{\gamma m}{v^2}$ to be virtually operative although it only 1/15 of the earth's radius, and that the su rounding oxygen density ρ_{O_2} is 10^{-25}), which amoun to about $1{\cdot}8 \times 10^{-3}$ gm. sec.$^{-1}$—a quantity unque tionably greater than the kinetic loss. (In the ca of the moon, or of Mercury, the kinetic loss is th greater and the earth loses hydrogen to the poi observed.)

Lest it should now be argued that too much oxyge in the air would be almost or quite as bad as none it can be shown that all the oxygen supposed to b in space (ρ_{O_2} near the sun is about 10^{-25}) can neve increase the atmospheric content by more than abou 23 per cent. For the solar space cell contains abou $1{\cdot}13 \times 10^{31}$ gm. of oxygen; and at a solar velocit of 20 km. sec.$^{-1}$ relative to its surroundings (it i probably less owing to similar movement of gas), th sun takes in gases 4×10^{10} times as fast as th earth, thus leaving only $2{\cdot}8 \times 10^{20}$ gm. of th oxygen total to accrue to the earth, which at presen has $1{\cdot}3 \times 10^{21}$ gm. (For a solar velocity relative t the gas of 10 km. sec.$^{-1}$ the possible increase woul be only 3 per cent.) A similar relation will hold fo any other gas, such as nitrogen or argon. Also th earth's iron core may act in a 'buffering' fashion absorbing most of any excess over the presen amount of oxygen.

The theological importance of the question of th future habitability of the earth was the origin of th studies here described—which evidently dispose of a reason for suggesting that the atmosphere is no permanent.

Thermal Decomposition of $HgCl_2$ Vapou

IN a recent communication, Gaydon[1] has show that an absorption spectrum obtained from mercur chloride ($HgCl_2$) in a heated steel tube by Rao[2], an attributed by the latter to diatomic HgCl (not to b confused with calomel (Hg_2Cl_2) which does not exis as a gas), is really due to CuCl (present as an im purity). It is the purpose of this communication t show by thermodynamic calculation that there is n chance at all of obtaining the absorption spectru of HgCl from thermally decomposed mercur chloride vapour. The same is true for HgBr an HgI. This may be surprising, because numerou diatomic radicals are known; for example, OH

NH, CN, CuH, CuCl, CaH, CaF, CaCl, BeF, MgF, MgCl, ZnF, CdF, AlF, AlH, SnF, PbF, PbCl, MnF, FeCl, the presence of which in thermal equiibrium at high temperatures has been ascertained by their absorption spectra. The rather exceptional position of the diatomic halides of mercury is primarily due to their small energy of dissociation, he value of which is 24,000 cal./mol. in the case of HgCl[3] and still lower for HgBr and HgI.

The free energy functions $(G^0-E_0{}^0)/T$ are accurately known for Hg and for Cl_2[4]. They can also be calculated with sufficient approximation for HgCl and for $HgCl_2$ vapour by using the molecular data published by me[3] and by Wehrli[5] respectively. These values at $T = 1{,}000°$ and 1,500° K. are given in Table 1.

TABLE 1. VALUES OF $-(G^0-E_0{}^0)/T$ IN CAL./MOL. DEGREE

T°K	$HgCl_2$	HgCl	Cl_2	Hg
1000°	74 06	64·67	55 45	42 83
1500°	79 71	68 16	58 88	44 85

The equilibrium constants K_p given in Table 2, ines 1–3, are then obtained from the equation

$$\log K_p = -\frac{1}{4{\cdot}573}\,\Delta G^0/T, \text{ where } \Delta G^0/T = \Delta E_0{}^0/T + \Sigma\,(G^0-E_0{}^0)''/T - (G^0-E_0{}^0)'/T.$$

($\Delta E_0{}^0$ is the heat of reaction of the (ideal) gases at 0° K.; the sum includes the free energy functions of the resultants.)

TABLE 2. DISSOCIATION OF $HgCl_2$ VAPOUR.

No.	Reaction	$\Delta E_0{}^0$ (cal.)	1000° K. K_p	1000° K. α(%)	1500° K. K_p	1500° K. α(%)
1	$HgCl_2 = HgCl + \frac{1}{2}Cl_2$	+ 51,900	$4{\cdot}59\times10^{-8}$	0	$2{\cdot}22\times10^{-4}$	0 5
2	$HgCl = Hg + \frac{1}{2}Cl_2$	− 4,600	$1\ 96\times10^{2}$	99·7	$1\ 02\times10^{2}$	99 4
3	$HgCl_2 = Hg + Cl_2$	+ 47,300	$9\ 00\times10^{-6}$	0·3	$2\ 26\times10^{-2}$	14 9
4	$HgCl_2 = Hg + Cl_2$ (experimental)[6]		$9\ 23\times10^{-6}$	0·3	$2\ 28\times10^{-2}$	14 9

It is seen from Table 2, lines 1 and 2, that in thermal equilibrium a dissociation of $HgCl_2$ into $HgCl + \frac{1}{2}Cl_2$ loes not take place to a measurable degree (α) even at high temperatures, because of the instability of he HgCl radical. On the other hand, the values of K_p calculated for the equilibrium $HgCl_2 = Hg + Cl_2$ line 3) are in excellent agreement (better than could be expected from an approximate calculation) with he experimental values (line 4) obtained by Braune and Knoke[6] from the thermal decomposition of $HgCl_2$ and represented by the equation $\log K_p = 5{\cdot}141 - 10{,}176/T$. At temperatures above 1,500° K. not given here) the dissociation of Cl_2 into 2 Cl has o be taken into account.

A more detailed paper including also the calculaions for $HgBr_2$ and HgI_2 will appear in *Helv. Chimica Acta.*

Loss of Antimalarial Properties in Quinine Degradation Products

KELSEY *et al.*[1] have described the preparation and properties of a "quinine degradation product" obtained by incubation of quinine with a suspension of rabbit liver tissue, and Mead and Koepfli[2] have reported on the chemical constitution of the product. These workers have not, however, determined whether or not this product is active against malaria parasites. We have therefore carried out the investigations described below on its action against infections of *Plasmodium gallinaceum* in chicks.

Experiment 1. Quinine was incubated with a suspension of rabbit liver, half the suspension being treated with sodium hydroxide prior to incubation to destroy enzyme activity. The untreated and 'control' materials were then extracted with chloroform, in which both the quinine degradation product and residual quinine were soluble. Suitable volumes of the chloroform extracts were measured into ampoules, the chloroform was evaporated off, and the ampoules containing the dry residue were sealed. Groups of chicks infected with *P. gallinaceum* received twice daily doses of the 'test' and 'control' material dissolved in the requisite volume of dilute hydrochloric acid immediately before administration. The extract from the suspension treated with sodium hydroxide contained 1·7 mgm. of residual quinine per ml.; that from the untreated suspension contained no unchanged quinine.

Experiment 2. Using a larger quantity of liver, a sample of the pure degradation product was prepared by a method similar to that of Kelsey *et al.*[1]; the melting point of the product was within 1° C. of that reported by them. The antimalarial activity of this sample in dilute hydrochloric acid solution was determined in comparison with that of a similar dose of quinine.

The results of the antimalarial tests are tabulated below. Only two birds were used in each group because of the small quantities of metabolic products available.

Expt. 1			Expt. 2		
Mean % red cells parasitized			Mean % red cells parasitized		
Untreated suspension	NaOH-treated suspension	Undosed controls	Quinine degradation product	Quinine	Undosed controls
83	0	71	84	82	88

These results show that the peripheral parasitæmia of chicken malaria is not reduced by administration of an extract of liver suspension in which all the added quinine is metabolized (and therefore presumably containing the quinine degradation product), nor is it reduced by doses of the pure degradation product. It may therefore be inferred that after administration of quinine in malaria treatment, a proportion of the alkaloid is converted by the liver of the host into an inactive metabolite. The amount of alkaloid converted *in vivo* is probably much greater than is converted in liver suspensions.

This metabolizing of quinine, with consequent loss of antimalarial activity, might be borne in mind in designing new derivatives or synthetic products of the cinchona type. We have indications, for example, that, while quinidine is metabolized similarly to quinine, cinchonine and cinchonidine are not metabolized by liver suspensions (chick liver). Mepacrine and plasmoquin also appear to be unchanged by rabbit liver suspensions.

A Convenient 'Bridge' for Two-Solution Cells

In the setting up of two-solution cells for the measurement of electromotive force, it is not easy to establish a satisfactory junction between the two liquids, so tedious and cumbersome devices, such as the agar jelly bridge, are commonly in use. The difficulty may be overcome, and stable and correct junction potentials obtained within a few seconds, by the simple device of using for the bridge a strip of filter paper, the ends of which dip into the two solutions, which may conveniently be contained in two small beakers resting on a block of paraffin wax.

If the filter paper be used dry, a liquid-liquid junction is immediately set up by capillary rise.

If it is desired to use a third liquid for the bridge, a strip of paper may be soaked in this, and the excess removed before use by pressing between dry filter papers.

If a galvanometer of high sensitivity is in use, a single strand of bleached cotton yarn will form a satisfactory bridge, and the device may be further improved so as to give readings which remain stable indefinitely, by drawing the yarn through a glass U-tube, so as to shield it from evaporation.

Chromium Oxide as a Promoter in Catalysts for the Fischer-Tropsch Synthesis

The economics of synthesis of hydrocarbons by the Fischer-Tropsch process may be improved by using (1) cheaper catalytic material, (2) water gas as such in place of enriched synthesis gas ($CO : H_2$ as 1 : 2) and (3) medium pressures instead of atmospheric pressures. A cheap iron-copper catalyst prepared by Ghosh and Sen[1] gave 86 gm. of hydrocarbons per cubic metre of gas and has since been developed by Japanese investigators[2]. The fact that chromium oxide possesses very high adsorption for hydrogen at 200° has been taken advantage of in preparing a catalyst ($Co = 34$ per cent; $Cu = 4$ per cent; $ThO_2 = 2{\cdot}3$ per cent; $Ce_2O_3 = 0{\cdot}24$ per cent; $Cr_2O_3 = 4{\cdot}6$ per cent; rest kieselguhr) which has been found to be remarkably steady, and yields with water-gas at a pressure of 5 atmospheres and 205° C. 160 gm. of liquid hydrocarbons per cubic metre with a space velocity of 600 c.c. per hour per c.c. of catalyst.

Darkened Violet in Colour Vision

EDRIDGE-GREEN[1] has directed attention to the shortening of the violet end of the spectrum which he found in some persons. A test of sensitivity to red, orange, yellow, yellow-green, green, blue-green, blue, violet and purple was carried out on 103 men and 104 women, excluding all red-green blind and red or green anomalous subjects. The experimen was performed with a form of colorimeter using the Ilford Monochromatic filters (601–8) and purple (501). Relative brightness was measured as well as sensitivity to hue.

Three women and three men had the violet darkened by more than three times the standard deviation of brightness levels of violet for the remaining subjects, which shows that the darkening was not due to norma variation (or random error). A number had slight darkening of violet and blue, but while there was a correlation of + 0·337 between blue weakness and darkening of blue, the correlation between violet weakness and darkening of violet was not significant This means that on the whole there was a tendency for blue to be darkened when it was weakened, while violet was as often brighter as darker when there was loss of sensitivity to its hue.

In this test there were about 10 per cent who had marked yellow-blue weaknesses and were not red green defectives (while the red-green blind are rarely weak in yellow or blue). This confirmed the result of previous tests. The yellow-blue weak subjects were not sufficiently defective to be called blue yellow blind and they were not consistently detected by tests in general use; but they had sometimes suspected a weakness of colour-sensitivity in themselves. Six of the yellow-blue weak subjects were those with darkened violet. Five of them were weak in yellow as well as in blue, and one in blue rather than in yellow. All were weaker in yellow and/or blue than in violet, but not weaker than the yellow blue weak in whom violet was normally bright.

Equality of proportion for both sexes suggests tha blue-yellow weakness and darkened violet are not sex-linked characters, a conclusion supported by genealogical data. Darkening of violet appears to be about as common in each sex as the familiar darkening of red (as in protanopes) among men. Just as, in my experience with detailed tests on about seventy red-green defectives, the protanopes are not 'red-blind' but are red-green defectives with darkened red as an additional character, so those with darkened violet are not 'blue-blind' but are yellow-blue defectives with violet and blue of diminished brightness

Thus, although there are, as Walls[2] has predicted two classes of blue-defectives, namely, those with and those without darkened violet, they are not, as he suggested, products of a shifting of violet sensitivity towards green (darkened violet), and of green towards violet (not darkened), respectively. They appear to be yellow-blue defectives in whom the violet is exceptionally dark.

Crystalline Hæmolytic Substance from Normal Blood

THE occurrence of a hæmolytic substance in normal blood has been demonstrated by Bergenhem and Fahraeus[1]. This substance was present in the ether precipitate of the alcohol-soluble fraction of serum, and was described by them as a lysolecithin, that is, a derivative of lecithin from which one fatty acid has been split off by the action of lecithinase, an enzyme analogous to that contained in cobra venom. However, the evidence in favour of the existence of lecithinase in serum and of the lysolecithin nature of the lytic substance was indirect, since no attempt at purification or isolation of either the lecithinase or the lytic principle has been reported.

The present work was concerned with the isolation of the hæmolytic substance from human blood plasma. The substance has been purified and finally obtained in a crystalline form. It is free from nitrogen, phosphorus, sulphur and halogen. It is insoluble in water but soluble in ether, and since it is free from nitrogen and phosphorus, it is not a lysolecithin. Molecular weight determination and microanalysis agree reasonably well with the suggested formula $C_{22}H_{42}O_5$; m.p. 45°. 0·1 c.c. of a 5 per cent erythrocyte suspension of human blood in 5 c.c. of isotonic phosphate buffer solution (*p*H 7·2) is completely hæmolysed in about one minute at 37° by 50 μgm. of the crystalline material, that is, in a dilution of 1 : 100,000.

A detailed account of the isolation, purification and chemical constitution of the crystalline material will appear elsewhere.

Respiration of Spermatozoa in Egg-Yolk Medium

OF various media used in artificial insemination for the preservation of the semen[1], the egg-yolk phosphate mixture of Phillips and Lardy[2] has given the best results, maintaining the fertilizing capacity of bull semen for several days at 5° C. Egg-yolk phosphate is also a good medium for maintaining oxygen uptake of the semen in respiratory experiments, and Walton and Edwards[3] found a positive correlation between oxygen uptake of semen samples and the fertility of the bulls from which the samples were taken. Experiments have therefore been undertaken to determine the factors present in the egg-yolk affecting the respiratory activity at 37° C., in expectation that the knowledge gained will assist in the discovery of the most favourable conditions of storage.

Semen was obtained from the bull by the artificial vagina[4]; 1 ml. of semen was used for each measurement of oxygen uptake in a Barcroft-Dixon manometer[5].

It was found that neither the cell-free seminal fluid nor the egg-yolk, either separately or in combination, gave any appreciable oxygen uptake. Whole semen (cells plus fluid) in phosphate buffer alone gave relatively good respiration. The addition of egg-yolk, however, greatly increased oxygen uptake, but in about one hour's time there was gradual decline. In order to trace the sources of this increase and of the eventual decline, the egg-yolk has been fractionated by various treatments and each fraction tested separately. The first fractionation was achieved by dialysing the egg-yolk in a 'Cellophane' tube at 1° C. against distilled water. Two fractions were thus obtained; the *non-dialysable portion*, which contained the bulk of the egg-yolk; and the *dialysable portion*, which passed through the membrane into solution. Both fractions were made isotonic, the first by re-dialysis against phosphate buffer and the second by evaporation at 50 mm. pressure until the volume was equal to the water content of the original yolk. The non-dialysable fraction gave a slightly reduced initial uptake in comparison with the untreated yolk; but the uptake continued at an almost constant rate for the remaining period of the experiment (3 hr.). The addition of the dialysable fraction to the buffered semen caused a slight initial rise, followed by a marked inhibition.

The two outstanding features of these experiments are: (1) that the non-dialysable portion is capable of maintaining a high respiratory rate over a prolonged period; and (2) that dialysis has removed from fresh egg-yolk a substance or substances which give rise to inhibition of respiratory activity, and that these are present in the dialysable portion. In regard to (1), we have further found that by extraction of the non-dialysable portion of the egg-yolk with organic solvents, both the fat-free protein residue and the re-emulsified fat increase the oxygen uptake when added to the semen-buffer system. There is some evidence that the degree of dispersion and the stability of the emulsion may contribute to the activating or preservative action of the fat in the egg-yolk. The unsaponifiable matter of the fat has a slightly inhibitory effect. In regard to (2), we have further investigated the nature of the inhibitory mechanism. An inhibitor itself is not present initially either in the untreated egg-yolk or in the dialysable portion, but is only gradually formed as a result of the oxidative metabolism of the spermatozoa on a substrate which is present in the dialysable portion. The inhibitor is not formed in the absence of oxygen.

Catalase, in relatively large amounts (at least 10 μgm.), completely reverses the inhibition. Peroxidase in smaller amounts has the same effect. Catalase inactivated by heat, cytochrome *C*, hæmatin, and ferrous ion had slight effects only upon the oxygen uptake and did not reverse the inhibition. Although the presence of free hydrogen peroxide could not be detected by the benzidine-peroxidase test, it is possible that the inhibitor is an organic peroxide and that catalase and peroxidase both reverse the inhibition brought about by this peroxide. The mechanism involved bears some resemblance to the 'coupled oxidations' of the type described by Keilin and Hartree[6]. The substrate of the inhibitor in the dialysable portion of the egg-yolk is soluble in ethanol but not in ether.

Since the non-dialysable portion of the egg-yolk maintains respiratory activity well, tests have been made of its capacity as a storage medium, and a number of cows have been inseminated with semen stored in it. Results are not yet complete, but so far have been satisfactory.

Our thanks are due to Prof. D. Keilin and Dr. T. Mann, of the Molteno Institute, for much help and advice, and to Mr. Rowson of the Insemination Centre for conducting the fertility tests.

Thiourea and the Suprarenal Cortex

Rats fed on diets containing thiourea and thiouracil die after varying periods of time. Some preliminary experiments showed that in the case of rats on 0·5 per cent thiourea, the action of the drug was reversible up to a certain stage; but after this, death occurred whether the animals were put back on to the control diet or not. This indicated that thiourea was exerting more than a simple antithyroid effect. Hughes[1] found similar results with thiouracil. We also observed in rats on both thiourea and thiouracil that in the terminal stages (the last two days) the suprarenals were frequently enlarged and dark reddish brown in colour. Except in the terminal stages, however, our findings confirm those of Williams, Weinglass, Bissell and Peters[2], who reported that in rats treated with thiouracil the suprarenals were smaller than normal although the ratio of gland-weight to body-weight was normal.

To test for possible suprarenal cortex deficiency, a batch of 26 young male rats, which had been on diet containing 0·5 per cent thiourea for 28 days and had remained stationary in weight for 14 days, was divided into four groups. All groups received the diet plus thiourea, one group being supplemented with thyroxine (10 μgm. thyroxine daily injected subcutaneously in alkaline saline), one group having 1 per cent sodium chloride to drink instead of tap water and one receiving 1 per cent sodium chloride to drink in addition to subcutaneous injections thrice daily of 0·1 ml. 'Eucortone' (suprarenal cortex extract). The average weights of these animals are given in the accompanying table.

Average weight of rats (gm.)

Group	Days on diet			
	30	60	90	120
Control	105	149	202	
Thiourea	52	All dead		
Thiourea + saline		68	All dead	
Thiourea + saline + 'Eucortone'		92	107	147
Thiourea + thyroxine		96	118	140

Thiourea diet supplemented after 30 days by giving saline to drink saline to drink plus three subcutaneous injections daily of 0·1 ml 'Eucortone' or 10 μgm. thyroxine subcutaneously daily.

All the rats receiving thiourea only died in a short time. The rats drinking 1 per cent sodium chloride gained some weight and lived longer than the rats drinking tap water. Those receiving both 1 per cent sodium chloride and injections of 'Eucortone' showed a remarkable recovery, as did also the rats receiving thyroxine. Although these two groups of rats were gaining weight at approximately the same rate, those receiving thyroxine were sleek and active whereas those on 'Eucortone' were somewhat lethargic. Neither group caught up with the control group in weight. The thyroids of the thyroxine-treated rats were normal, whereas gross and histological examination of the thyroids of the rats treated with 'Eucortone' showed that these animals were still in a hypothyroid condition. The growth of these animals can presumably be attributed largely to retention of water and increased food-intake. One rat treated with thiouracil, which had remained more or less stationary in weight for thirteen weeks, also recovered after injecting 'Eucortone' (0·1 ml. thrice daily). In six weeks, this rat increased in weight from 116 gm. to 164 gm. and was then killed for histological examination.

The results of these preliminary experiments indicate that both thiourea and thiouracil produce suprarenal cortex deficiency in rats. This view is supported by the fact that histological examination of the suprarenals of rats in the terminal stages frequently revealed abnormalities in the cortex including severe congestion, particularly of the zona reticularis, depletion of lipoids (stainable with Scharlach R), hæmorrhages and sometimes areas of necrosis. The glycogen contents of the livers were also considerably reduced.

The exact mode of action of thiourea and thiouracil on the suprarenal cortex has not yet been established.

I am indebted to Dr. C. L. Oakley, who carried out all the histological examinations.

Palolo Worms

I have been much interested in the communications in *Nature* concerning the palolo worm, sent by Commdr. William Burrows[1] and by Mr. R. A. Leven[2]. I should like to direct attention to the paper published nearly forty years ago by W. McM. Woodworth, in which the distribution, habits, structure and history of the palolo are fully discussed. It was published in 1907 in the *Bulletin of the Museum of Comparative Zoology*, 51, No. 1, 1–21, pls. 1–3. As it was based largely on Woodworth's own observations, it is of real importance and should not be forgotten or overlooked.

RESEARCH AND DEVELOPMENT IN THE BRITISH COLONIES

UNDER the title "Colonial Research 1944–45"[*], there have now been issued the second annual reports of the Colonial Research Committee and of the Colonial Products Research Council, and the first annual report of the Colonial Social Science Research Council; for convenient record, these reports will in future be published in a single volume. Following on the reports of the Commissions on Higher Education in the Colonies and in West Africa (see *Nature*, Sept. 27, p. 373), they assist materially in appraising the recommendations of those Commissions in regard to Colonial research; and although the Colonial Research Committee's report is not concerned with fundamental principles of policy to quite the same extent as its first report, the present report is of scarcely less general interest.

With the establishment of the specialist research committees, the main work of organization in Britain for Colonial research may be said to be well advanced. The main bodies, including a forthcoming committee for Colonial agricultural, animal health and forestry research, are directly advisory to the Secretary of State, who nevertheless looks to the Colonial Research Committee for advice on general research policy, and the Committee considers that its future work lies rather in certain co-ordinating functions which only a centrally placed body can perform. It has, first, to ensure so far as possible that no important field of inquiry is overlooked because it does not fall well within the scope of one or other of the specialist bodies; and, secondly, to maintain a proper balance in the allocation of effort and funds.

The first function is comparatively simple, and the Committee instances the study of the needs of housing research, for which purpose a Colonial Housing Research Group, with Dr. I. E. Evans of the Building Research Station as chairman, was established. The Committee is also proceeding to a study of the needs of zoological and botanical surveys, in so far as these fall outside the direct scope and interest of agricultural and veterinary research. Other subjects mentioned as worthy of attention are: road research, a study of the power resources of the Colonies of all kinds, potential as well as actual, and the possible application of land utilization survey techniques. In regard to the second function, while the sum of £500,000 made available for research under the Colonial Development and Welfare Act of 1940 has so far been substantially underspent, and with the Act of 1945 that provision becomes £1,000,000 a year, the possibility of any financial limitation of Colonial research effort seems remote, since the Committee proposes to adhere to its policy of supporting only well-conceived schemes for which adequate and suitable personnel are available. Nevertheless, the end of the War will release many research workers, and the proposed research services alone may be expected to cost substantial sums, even if Colonial governments make some contribution. Moreover, plans laid and decisions taken now are likely to have a very important effect on future trends of research policy; and, discussing the choice of the precise means to be adopted, the Committee points out that even the urgent problems do not always yield most readily to a frontal assault. The key to a particular problem, or indeed to a whole complex of problems, may lie in fundamental work in some apparently quite unrelated field. In terms of Colonial needs, it may sometimes be wisest to concentrate effort in the laboratory best equipped to deal with the key problem, wherever that problem may be; and how to discern such key problems is in itself a major problem to the solution of which the Committee proposes now to address itself.

Reviewing the fields of research, the Committee endorses the recommendations of a sub-committee of the Colonial Survey and Geophysical Committee for creating a central organization designed to complete the whole of the geodetic and major framework and half of the outstanding topographical work, making the utmost use of aerial photography. The Royal Air Force is prepared to carry out the air photography on behalf of this survey as part of its peace-time specialist training. The Committee also endorses the recommendations of a Committee on Colonial Geology for a central organization on similar lines, and the two sets of proposals provide an unrivalled opportunity of supplying the Colonies with a thorough and accurate basic knowledge of their most important resources. The Committee has also recommended a capital grant towards the cost of the fisheries research station being installed in Mauritius, as well as the acceptance of the proposals of the Colonial Fisheries Advisory Committee for the formation of a Colonial fisheries service, to be recruited on terms of service analogous to, and interchangeable with, the federated superannuation system for universities.

The Committee considered a full report from an *ad hoc* sub-committee of the Colonial Advisory Council of Agriculture, Animal Health and Forestry, and supports its recommendation for the establishment of a separate committee of specialists to advise on research in these fields and to take over such functions from the Council itself. This recommendation has been accepted by the Secretary of State. A second recommendation, that in the Colonies themselves research should be organized on a regional rather than a territorial basis, has been commended to Colonial Governments, and a third recommendation for the establishment of a separate research service on the lines proposed for the fisheries service has been deferred for consideration by the new Committee. Schemes were also made for continuing the low-temperature research station at the Imperial College of Tropical Agriculture, for research on animal diseases in the Bechuanaland Protectorate, and for a survey of animal diseases in Zanzibar.

No specific schemes for medical research involving substantial expenditure were before the Committee during the year, but schemes were made for continuing studies on the bionomics of *Anopheles gambiæ* in Sierra Leone and Nigeria, and for D.D.T. field trials, for which £4,500 was provided. The latter scheme points the way to what may become a major development in tropical preventive medicine; workers in Africa, advised and guided by Prof. P. A. Buxton, have shown that D.D.T. is toxic to the tsetse fly. Important trials designed to work out effective techniques for its application in the field have been planned. The Committee has also recommended the adoption of an important scheme for research and development work on growing cinchona in the Colonial Empire, based in East Africa; in regard to medical research in general, the Committee considers that, so far as central organization is concerned, the way is now clear for a rapid and systematic attack on the major medical problems of the Colonies. It is pointed out, however, that research cannot be prosecuted effectively in this or in any other field without a regular flow of skilled men of science, and, unless energetic steps are taken, one of the chief shortages is likely to be in the field of entomology.

---

[*] Colonial Research 1944–45 1. Colonial Research Committee, Second Annual Report, 2 Colonial Products Research Council, Second Annual Report; 3. Colonial Social Science Research Council, First Annual Report. (Cmd 6663.) Pp. 32. (London . H M Stationery Office, 1945.) 6*d* net.

Other special committees established are the Tsetse Fly and Trypanosomiasis Committee and the Cocoa Research Committee, while with the aid of a grant of £28,000 now made on the recommendation of the Committee, it is intended to place the Anti-Locust Research Centre on a more permanent and satisfactory basis. Under the direction of an advisory scientific committee, the Centre will carry out a development programme covering the collection and dissemination of information (in close collaboration with the Imperial Institute of Entomology), research and technical advice in the conduct of specific campaigns. Proposals for continuing and extending the work of the Discovery Committee, which has done magnificent work on the oceanography and marine biology of the southern seas, were also considered. A list of schemes recommended and finally approved during April 1, 1944–March 31, 1945 is appended.

The report of the Colonial Products Research Council refers to the visit of Sir Robert Robinson and Prof. J. L. Simonsen, the director of research, to the West Indies; they were accompanied on most of their tour by Dr. A. King, head of the British Commonwealth Scientific Office in Washington. Further insight into American methods of industrial development was obtained during visits to Puerto Rico and St. Thomas, and during a visit to Trinidad a detailed programme of research was worked out with Trinidad Leaseholds, Ltd., while it was suggested to the directors of the British West Indies Sugar Association (Inc.) that the formation of an industrial research organization for sugar technology might be of great value. In a visit to British Guiana, it was suggested that difficulties being encountered in schemes for agricultural development owing to the high incidence of malaria in the coastal strip offer an ideal opportunity for an experiment on the use of D.D.T., and according to preliminary reports the experiment has met with a measure of success. Correspondents with the director of research have been appointed in all the Colonies of the Caribbean. A major development during the year was the decision of the Council to open a Microbiological Research Laboratory in Trinidad; Dr. A. C. Thaysen has been seconded to work under the Council and direct the research of this new laboratory, which it is anticipated will provide a centre for fundamental microbiological research in the tropics.

Reviewing research work in progress, the report refers to the investigation of expressed lime oil, which has been shown to contain limettin, *iso*pimpinellin, bergaptol and 5-geranoxy-7-methoxycoumarin, and these crystalline constituents are now being examined as antioxidants. Work on the reactions of eugenol and its derivatives from clove oil has been actively pursued, and at the Chemical Research Laboratory of the Department of Scientific and Industrial Research Dr. L. P. Walls has studied the most suitable methods for determining the ergosterol content of yeasts and for its extraction. Work on the utilization of sucrose has been actively pursued under the direction of Prof. W. N. Haworth and Dr. L. F. Wiggins, attention being directed mainly to lævulinic acid, hydroxymethylfurfuraldehyde, and to the dianhydrides of mannitol and sorbitol. A large number of new substances prepared appear likely to find application as chemotherapeutic agents or in the plastics industry. Work has also been commenced in the starch field, while in that of theobromine some attention has been given to the reaction of chlorotheobromine with diamines as a route to high polymers and to a process for reducing the theobromine content of cocoa meal to about 0·1 per cent by solvent extraction after treatment with ammonia. The utilization of Wallaba wood resin and the study of vegetable oils from Colonial sources have also received attention, and a list of some important plants found in the Colonies which are likely to have medicinal or insecticidal interest is undergoing final revision.

The Colonial Social Science Research Council, which was constituted in June 1944, held eight meetings during the period to March 31, 1945, covered by its first report. The general functions of the Council comprise broadly the review of the organization of research in the social sciences in the Colonies, the scrutiny of research projects submitted to it, the making of recommendations as to the publication of the results of research and the initiation of research in fields not otherwise covered. The Council was constituted to represent the main branches of the social sciences; but economic research is covered by the Research Sub-Committee of the Colonial Economic Advisory Committee, the chairman of that Sub-Committee being a member of the Council.

Attention is directed in the report to the need for certain types of basic data as being fundamental to many of the inquiries with which the Council is concerned, for example, the provision of sound demographic data, including census and vital statistics.

Further, the great bulk of the material required for effective study of the form and operation of political and administrative institutions consists of records in official archives, which at present are not always readily accessible without interfering with administrative work. The Council has also devoted much consideration to the attempt to ascertain what are the main research problems in the various fields, and what order of priority should be attached to them. While a comprehensive research programme has not yet been formulated, several problems have been recognized as major research needs. There is urgent need, for example, for surveys of social and economic conditions in urban and in rural areas; for comparative studies of local government; for studies of the social and economic effects of migratory labour in Africa, of land tenure in relation to agriculture and social structure, of Colonial administrative law, particularly in respect of procedure in native courts, of political development in 'plural' communities; and for sample surveys of literacy in relation to programmes of mass education. A wide range of intensive research on individual languages and cultures of many Colonial peoples is also required.

Attention has also been given to the organization of research. For some time to come, much research in the social sciences in the Colonies must be undertaken by individual workers; but the Council realizes the value of the more integrated organization provided by local or regional institutions specifically adapted for research into social problems, and believes that more institutes such as the Rhodes-Livingstone Institute and the Sociological Department of the West African Institute of Industries, Arts and Social Sciences will be necessary. The Council has so in mind the need for close integration, first with the practical knowledge and requirements of governments as expressed in development and welfare programmes, and in the work of administrative officers nd officers of the specialist services, and secondly, ith the research programmes of other organizations n the same field. Reference is made, however, to he present extreme shortage of senior research workers fitted for independent and responsible investigation in these fields; the Council considers that or some time to come it will be necessary to draw most of the workers required from Britain. To enable any comprehensive programme of social research to e undertaken, postgraduate training of research workers on a long-term basis will be necessary, presumably at the universities; but in the present emergency the Council contemplates the provision of hort-term training, appropriately planned with the ultimate objectives in mind and financed under the esearch section of the Colonial Development and Welfare Act. Reference is also made to the real problem which the future career of the research worker may offer, and the scarcity of openings when the investigator has completed his specific project.

Of specific research projects examined by the Council, reference may be made to work on the handbook of African languages, the ethnographic survey n Africa, research work on economic and social spects of Colonial policy during the war period and Dr. R. R. Kuczynski's "Demographic Survey of the British Colonial Empire".

INDIAN FISHES AND FISHERIES

DR. SUNDER LAL HORA has added much, and is still adding, to our knowledge of the fishes of India. In a series of papers published during 1942 onwards, sometimes in association with other authors, he has dealt with a variety of subjects.

Discussing the respiratory movements of some Homalopterid fishes[1], attention is directed to the lose parallelism between the accessory respiratory chambers of these and the bucco-pharyngeal hambers of certain air-breathing fishes. The fishes of Poona[2], with their Hindi names and distribution[3], and the fishes of Mysore and adjoining hill ranges[4] are listed. Notes on fishes in the Indian Museum[5] and descriptions of the large-scaled barbels, already discussed in six previous articles, are continued[4,6,7].

In May 1942, Dr. Hora was appointed to the post of director of fisheries, Bengal. One of his first ctivities in this capacity was a thorough investigation into the pollution of streams by the effluent of the quinine factory at Mungpo and its effect on the sh. The report[8] deals with many aspects of the problem, the main conclusion being that the effluent eads to the pollution of the streams affected by it (in the sense that the stream waters do not remain natural) not so much through the chemical waste products contained in it, but by the deposition of bark residues in the form of a coloured flocculent matter of very fine consistency, and by the oil contained in the effluent. Although there may be seasonal depopulation of the streams due to pollution, he fish are not permanently injured and their breeding is not affected. The main recommendations for improvement are, so far as practicable, to remove the bark residues by sedimentation in settling tanks and possibly to recover more oil by skimming the tanks. With the construction of these tanks it may be possible to let out the effluent over a longer period, so that only a small quantity passes through the stream at a time.

Dr. Hora is always an advocate for research in all its aspects, and three of his papers[9,10,11] show the great need for biological stations in India and above all urge the plea for the establishment of a fishery research institute. In post-war reconstruction a central organization to deal with the fisheries of the country is the obvious solution.

CHEMISTRY IN CHINA

THE four volumes of the *Journal of the Chinese Chemical Society*[1] covering the years 1941–44 contain more than a hundred papers on all branches of the science. Many of the papers deal with problems of nutrition, vitamin content of food, fertilizers and soil types in China, and the analysis of Chinese drugs. There are investigations of the properties of vegetable gasoline made from native materials, cracking of vegetable oils, and the oxidation of natural fats and oils. The indican content of Szechwan indigo, the fixation of Chinese valonia by hide powder, and similar problems have been studied.

A large number of papers are of general chemical interest, as distinguished from those concerned with national requirements, and a very good balance is preserved between the various branches of investigation. In organic chemistry, the papers on amino-acids, the synthesis of products from ethyl alcohol, acetaldehyde, from acetylene, ketones, the santonin series, enzymes and sulphanilamide derivates, may be mentioned. Several papers on analytical chemistry, including the use of the polarograph, are of interest. In physical chemistry, the papers are mostly theoretical, dealing with such subjects as ionic volumes, radii and entropies, apparent heat capacities of salts in solution, ionic polarization and refraction, electronegativity and atomic number, viscosity and critical data. Several interesting new equations are proposed relating to these magnitudes. A paper on the temperature of maximum density of heavy water fixes this at 11·21°, in good agreement with other recent investigations. There are some papers on chemical kinetics (iodine monochloride addition and unsaturated acids) and optical rotation.

The standard of the papers is high, and the record of work, some at least of which must have been carried out in difficult circumstances, is impressive. The future contributions of China to chemistry should be of great value if the present rate of progress is continued.

*(Meetings marked with an asterisk * are open to the public)*

Monday, October 29

Institution of Electrical Engineers (at Savoy Place, Victoria Embankment, London, W C 2), at 5 30 p m —Discussion on "Should Engineering Concerns be Managed by Engineers?" (to be opened by the President).

Chemical Society (joint meeting with the Swansea University College Chemical Society) (in the Chemistry Lecture Theatre, University College, Swansea), at 6 p.m.—Prof J. Kendall, F.R.S.: "The Separation of Isotopes and Thermal Diffusion".

Chemical Society (joint meeting with the Local Sections of the Royal Institute of Chemistry and Society of Chemical Industry) (in the Engineers' Club, Albert Square, Manchester), at 7 p.m.—Mr. F. P. Dunn . "The Publications of the Three Chartered Bodies".

Royal Geographical Society (at Kensington Gore, South Kensington, London, S.W.7), at 8 p.m.—Brigadier Bernard Fergusson : "Beyond the Chindwin—the Wingate Expeditions into Burma, 1943 and 1944".

Tuesday, October 30

Chadwick Public Lecture (at the Livingstone Hall, London Missionary Society, 42 Broadway, Westminster, London, S.W.1), at 2.30 p m —Dr Walter P. Kennedy: "Health Education, its Problems and Methods".*

Sheffield Metallurgical Association (at 198 West Street, Sheffield 1), at 7 p.m —Mr A. Muir · "Furnace Automatic Control".

British Institution of Radio Engineers, Scottish Section (at the Royal Technical College, George Street, Glasgow, C.1), at 7.30 p.m.—Dr Paul Vigoureux: "Quartz Oscillators".

Wednesday, October 31

Imperial Institute (South Kensington, London, S.W.7), at 3 p m. —Dr. F. Dixey, O.B.E . "Nigeria, its Geology and Mineral Resources".*

Thursday, November 1

Chemical Society (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr L. Hunter "Mesohydric Tautomerism", Mr. A. G. Foster: "The Sorption of Condensable Vapours by Porous Solids", Part 3. Multimolecular Adsorption, Part 4 Linear Isothermals and the Langmuir Equation; Mr A. Campbell and Mr. J. Kenyon · "Retention of Asymmetry during the Beckmann, Lossen and Curtius Changes".

Royal College of Surgeons of England (at Lincoln's Inn Fields, London, W C.2), at 5 p m.—Sir Arthur MacNalty: "The Renaissance, its Influence on English Medicine, Surgery and Public Health" (Thomas Vicary Lecture).

Royal Institution (at 21 Albemarle Street, London, W.1), at 5 15 p m.—Prof. James Gray, F.R.S : "The Anatomy and Functions of the Brain in Lower Vertebrates" (i) "Fishes".

Institution of Electrical Engineers (at Savoy Place, Victoria Embankment, London, W.C.2), at 5 30 p.m.—Mr. P. B. Frost and Mr. E. F. H. Gould · "Practical Aspects of Telephone Interference arising from Power Systems".

Institute of Welding, Portsmouth Branch (at the Gas Company Offices, Guildhall Square, Portsmouth), at 7 p m.—Mr. W. G. John: "Progress in the Application of Welding to Ship-building".

Friday, November 2

Royal Institution (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Mr. A. C. Hartley . "Laying a Pipe-line under the Channel —Operation Pluto".

North-East Coast Institution of Engineers and Shipbuilders (in the Literary and Philosophical Society's Lecture Theatre, Newcastle-upon-Tyne), at 6 p.m.—Sir Lawrence Bragg, F.R.S.: "Problems of the Metallic State" (Andrew Laing Lecture).

Chemical Society (in the Chemistry Lecture Theatre, University College, Nottingham), at 7 p.m.—Prof. E. L Hirst, F.R.S. "Some Problems in the Chemistry of the Polysaccharides".

Institute of Welding, South London Branch (at the Borough Polytechnic, Borough Road, London, S.E.1), at 7.30 p.m.—Inaugural Meeting. Mr. H. W. G. Hignett: "Some Thoughts on the Weldability of Alloy Steels".

Saturday, November 3

Association of Austrian Engineers, Chemists and Scientific Workers in Great Britain (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 3 p.m.—Meeting of British and Austrian scientists in support of the restoration of Science in Austria.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned

Photographer to take charge of the Photographic Department—The Secretary, Royal Cancer Hospital (Free), Fulham Road, London, S.W.3 (October 31).

Physicist to assist in work of advisory and employment service for men and women in this profession—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 473, York House, Kingsway, London, W.C.2 (October 31).

Deputy City Analyst—The Medical Officer of Health, Depa ment of Public Health, Kenwith Lodge, Westbury Park, Bristol, endorsed 'Deputy City Analyst' (November 3).

Assistant Constructional Engineers by an important firm Engineers and Contractors for service at home and abroad (should qualified Civil Engineers with experience in Steam, Oil and Hyd Power Stations and Transmission Line Construction)—The Minist of Labour and National Service, Appointments Department, Techni and Scientific Register, Room 670, York House, Kingsway, Londo W C.2, quoting E 1968 XA (November 5)

Teachers (2) of Mechanical Engineering Subjects, and Teacher of Building Subjects, in the Rotherham College of Tec nology—The Director of Education, Education Offices, Rotherha (November 5).

Assistant Lecturer in Mechanical Engineering, and Assistant Lecturer in Textiles preferably with special qualific tions and experience in Spinning—The Principal, College of Tec nology, Belfast (November 7).

Lecturer in Mathematics in Royal Aircraft Establishme Technical College—The Ministry of Labour and National Servic Appointments Department, Technical and Scientific Register, Roo 670, York House, Kingsway, London, W.C.2, quoting A.1143 (November 8)

Lecturer in Civil and Mechanical Engineering, and a Lectur in the Biological Sciences (Botany, Zoology and General Physiolog —The Principal, West Ham Municipal College, Romford Road, Stra ford, London, E 15 (November 10).

Engineering Assistant in the office of the City Surveyor—T City Engineer and Surveyor, Town Hall, Leicester (November 10).

Lecturer in Civil Engineering—By *Air Mail* to the Registra University of the Witwatersrand, Johannesburg, South Afri (November 12—duplicate application should be lodged with t Secretary, Universities Bureau of the British Empire, c/o Universi College, Gower Street, London, W.C.1)

Chief Engineering Assistant—The Chief Engineer, Southe Waterworks Company, 13 Cambridge Road, Southend-on-Sea (Noven ber 15)

Chief Superintending Engineer (Ref. No. C.2840 XA), and Mechanical Engineer (Ref. No. C.2842.XA), for a Paper Mill India—The Ministry of Labour and National Service, Appointmen Department, Technical and Scientific Register, Room 670, Yor House, Kingsway, London, W.C.2, quoting the appropriate Ref. N (November 16).

Geologist by the Geological Survey of the Sudan Governmen for service in the Sudan to carry out general geological surveys an special hydrological and soil erosion studies, also supervision of wat development work—The Ministry of Labour and National Servic Appointments Department, Technical and Scientific Register, Roor 670, York House, Kingsway, London, W.C.2, quoting F 5043 (November 17).

Lecturer (full-time) in the Department of Metallurgy of th County Technical College, Wednesbury—The Director of Educatio County Education Offices, Stafford (November 17).

Assistant Librarian in the College Library—The Registra University College, Leicester (November 19)

Senior Research Metallurgist to the Tata Iron and Ste Company, Ltd., Jamshedpur—The Ministry of Labour and Nation Service, Appointments Department, A 9, Room 670, York Hous Kingsway, London, W.C.2, quoting F 4979.XA (November 19).

Lecturer in Pathology to dental students, and a Lecturer i Physiology to dental students—The Registrar, King's Colleg Newcastle-upon-Tyne (November 24).

Lecturer in Production Engineering, and a Lecturer-in Charge of Coal Mining Department, of the Technical Educatio Branch, Department of Public Instruction, New South Wales—Th Acting Official Secretary, New South Wales Government Offices, 12 Strand, London, W C.2 (November 30)

Technical Assistant in the Electricity Department—Th General Manager, Electricity Offices, Ferensway, Kingston-upon-Hu (November 30).

Research Fellowship to be held at the Bernard Price Institut of Geophysical Research, University of the Witwatersrand—By *A Mail* to the Registrar, University of the Witwatersrand, Johannesbur South Africa (November 30).

Lecturer in Geography, a Lecturer in Physics, and Lecturer in Political Science, in the Victoria University Colleg Wellington, New Zealand—The Secretary, Universities Bureau of th British Empire, c/o University College, Gower Street, London, W.C. (November 30)

Chair of Applied Mathematics in the University of Sydney-The Secretary, Universities Bureau of the British Empire, c University College, Gower Street, London, W.C.1 (November 30 Sydney).

Assistant Mycologist for indexing and editorial work—T Director, Imperial Mycological Institute, Ferry Lane, Kew, Surrey.

Graduate Assistant to teach Junior Mathematics in the Tec nical Day School and Senior Mathematics to part-time and evenn College students, and a Graduate Assistant to teach Geograph in the Technical Day School and Technical College, of the West Hartl pool Technical College—The Chief Education Officer, Education Office Park Road, West Hartlepool.

Lecturer (full-time) in the Department of Mechanical Engi eering—The Principal, · Borough Polytechnic, Borough Roa London, S.E.1.

Teacher of Chemistry and Allied Subjects, and a Teache of Physics, Engineering Science and Building Science—T Principal, Technical Institute, Tunbridge Wells.

Teacher for the Mechanical Engineering Workshop and f Mechanical Engineering Subjects, including Workshop Tec nology, in the Northampton College of Technology—The Ch Education Officer, Education Office, Springfield, Cliftonville, Nort ampton.

Librarian (temporary) in the Department of Agriculture f Scotland—The Regional Appointments Officer, Regional Appoin ments Office, Ministry of Labour and National Service, 5 Rothes Terrace, Edinburgh, quoting Ref. No. 352.M.

ARMY EDUCATION

EDUCATING THE EDUCATORS

A CENTRAL institute for the ambitious scheme of education in the British Army has recently been opened at Eltham Palace, Kent (see p. 527)—an occasion which gives rise to certain thoughts and queries about the nature and progress of this all-important aspect of present-day army life. As Major Hawkins, the chief instructor at the new School, states in his article, this "infant which was perfectly conceived some months ago, is now going through all the pangs of infancy". The same can be said of army education in general, for though there have been some attempts at it for several decades, they have been of a rather minor character and so many new projects have arisen *de novo* in recent years that one might say the general scheme of army education is still in its infancy. In bringing up any infant, too many advisers might leave both parents and child in such a state of confusion as to cause disaster; nevertheless, it is to be hoped that the parents of this infant will look for criticism from as many authorities as possible and for a long time to come, for there are many authorities on adult education outside the Army. Furthermore, if the various new schemes for education in the Army are based on sound principles, we may visualize army education in due course proving to be one of the most important of all projects in adult education. In this connexion it is gratifying to note that a number of H.M. inspectors (Ministry of Education) are to give the army education authorities the benefit of their experience and criticism after spending some time examining army education in the field. We trust, however, that these specialists will bear in mind that they are dealing with an experiment in adult education and not school teaching—for there is considerable difference between the two.

This immediately raises a very important point. It is to be hoped that the army authorities will always bear in mind that the principles and practice of education as accepted and applied in all good schools in Britain are not altogether suitable for education in the Army. Neither can army education be compared with university education, not even, we think, in the new 'formation colleges'. The logical corollary to this is that a school teacher is not necessarily the best choice for an army education officer. This must be mentioned, for too often it has appeared to be tacitly assumed that if there is a former school-teacher in an army unit, then he is the obvious choice for dealing with education in that unit. It should be borne in mind, however, that when appointing officers to take over responsibility for education among such a heterogeneous group as an army unit, a former school teacher, though experienced and probably well informed in the principles and practice of education of the child, may not be gifted with the tact, common sense and human understanding so essential when dealing with men. Very different methods of attracting an audience and in presenting the material are required; furthermore, the immediate and ultimate aims are very different also. This is important, for in due course we hope to see the majority of army men genuinely wishing to attend the classes arranged for them; then, and only then, will it be possible to eliminate the objectionable practice of rounding up a sufficient number of men to make up an audience, especially in the case of a visiting civilian lecturer. This practice can never ensure that the right men have been given the chance to derive whatever benefit there might be in attending such lectures. Neither is it calculated to encourage a visiting lecturer to agree to giving his services again. It all boils down, as will be evinced again further on, to the great need for preparing and tending the ground beforehand, and this can be done only by carefully selected education officers who in their turn have the sympathetic guidance and assistance of their seniors.

This raises the more general question of choice of personnel for tackling the problem of army education. The War Office and the Army have the benefit of the advice and help of certain qualified educationists both at the War Office itself and in the Central Advisory Council for Education in H.M. Forces. Individual specialists, too, have given assistance. But, in spite of what Major Hawkins claims in his article, we suspect that army education is all too frequently the victim of that 'red tape' with which the War Office and army life in general are so notoriously fettered. Advice and suggestions are, of course, essential: but it is not much use seeking these if they are to be carried out by army personnel who are not equipped with the necessary knowledge and experience or, worse still, who are periodically meeting the stumbling block of indifference on the part of their senior officers. We would therefore ask: Is the War Office satisfied that all senior officers concerned with army education are qualified in the modern principles of the science of adult education and able to appreciate, understand and carry out the proposals made by those specially qualified to make them? If not, then it seems desirable that the War Office should carefully scrutinize the methods and routine adopted in appointing and promoting army officers to carry out this work.

Of course, it must be realized that the Army is not primarily an academic institute, and army education must dovetail into the other aspects of army life. But such a realization is essential not only among the critics of army education but also among the army educationists themselves, lest the latter bite off more than they can chew and, indeed, trespass on the preserves of others. In war-time, educational schemes must be constantly under revision and subject to modification, sometimes even cancelled in face of more urgent needs—all with understanding and without complaint from the army educationists. In peace-time, this aspect of the problem cannot be so acute; but always must there be sympathy and complete understanding by the senior officers in charge of a unit, including its education officers. They must at any rate recognize the importance of army education, even if they are unable to take part in it, and thus give every facility within their power to the educationists under their command. Some senior men do so, and, in the field, the encouraging influence of their obvious interest in what is going on is s profound as to inspire not only the education officer but also the men to give of their best and to be on th constant look-out for new ideas.

Alas, on the other hand, other senior men seen merely to accept the educational side of arm life as a necessary nuisance wished upon them This is a pity, for then the orders are given an no further interest shown, leading to disconten and bitter feeling among the men who are doin their best for the cultural and technical educatio of the troops under unfortunately trying conditions. Furthermore, such indifference causes irritation among visiting specialist lecturers who a willing to help the War Office in its commendab attempts to raise the standard of education amon our troops. This complaint has sometimes bee viewed differently, and visitors have been accused demanding the 'red carpet to be laid down for them We doubt if this accusation can be made agains many visiting lecturers; they are probably merel resenting the superior and indifferent attitude whic greets them—and rightly so. It is now well know that in an attempt to assist soldiers in retaining an expanding their educational and cultural horizon during the War, the War Office has given facilities t civilian specialists who have agreed to visit the variou units at home and overseas to talk to, and have discussions with, the men in the field. There is no doub whatever that provided the problem is tackled in th correct manner, such a lecturer receives a since welcome from most officers and men. But it must b recorded that at times, before getting at the me themselves, it has proved necessary to break throug the obstacles of indifference and misunderstandi presented by senior officers. It is to be hoped th in due course the War Office will see its way clear rectify this deplorable situation; for it is undesirab that the indifference of a few senior officers shou entail the men losing those cultural contacts th clearly desire through visiting lecturers being di couraged from giving their services. It should made clear by the War Office to all senior officers th army education is to be taken seriously, and not mere treated as one means of giving the men something do during quiet periods, or as a Cinderella amo the multitudinous activities of modern army life.

The task of the Army Educational Corps is "inspire and organize education in the Army But the Army's teachers cannot carry out this t mendous and commendable project unless they a qualified by training or experience or both to do neither can they be expected to give of their b unless inspiration comes to them in the form sympathy and practical assistance and interest fr their seniors. Also, though in due course we mig reasonably expect army education to be organiz and carried out within its own ranks, there shou always be a welcome for the visiting civilian lectur To this end, army education officers *in the field* shou be encouraged to make contact with all acaden institutions within the vicinity of their units, a thus enable more direct cultural contacts to be ma between the Army and the civilian educational bod

These observations from education in the field must be taken into consideration if army education is to be viewed in its correct perspective and a true value assessed. Periodically, for example, there is published a statistical account of single lectures and courses of lectures arranged for H.M. Forces by the Central Advisory Council. This conveys only one aspect of he whole movement. What is also required by those interested is a mass observation of these lectures in action; returns concerning the number of men and women, voluntarily attending such lectures might cause some lifting of eyebrows. (Lectures attended under compulsion cannot reveal very much in this connexion.) The reactions of the men themselves, oo, would tell a valuable tale—one more valuable han a mere record of number of lectures arranged. The figures given by Sir Ronald Adam, adjutant-general to the Forces, in his speech at the opening of he new School, should be interpreted with the same reserve. According to Sir Ronald, about half the units in commands at home, 66 per cent of the field force units in the C.M.F. and 70 per cent of the Rhine Army have begun to implement the education scheme for the release period. Notwithstanding the difficulies of materials, printing and transport, already nearly a million text-books and books for unit and command libraries have been dispatched to formations and units. These figures are impressive, and the authorities are to be congratulated on their zeal. t is not for us to discourage such work this end by aising hares; nevertheless we are still disturbed about the other aspect of all this. Is the War Office satisfied that so far as is humanly possible the right men are in charge of the schemes in the field, and have the best men been chosen for seeing that the maximum benefit is derived from the reading of those million books ?

A similar point of view may be adopted concerning he masses of literature published in the form of pamphlets. The fact that so many hundred thousand A.B.C.A. pamphlets have been published and dispatched reveals little more than the commendable enthusiasm of the authors of them and the efficiency of the army and other authorities in conceiving and devising them. It is the receiving end which really counts, and when one sometimes hears that a pamphlet has been indifferently handled in an officers' mess and then given to one man with orders to 'mug it up' and give a lecture on it the next day, we wonder whether a little more propaganda among the officers in charge and some 'education of the educators' might not so enhance the value of the pamphlets as o render them more commensurate with the time, paper and money spent on them. A bigger harvest might be reaped if one could be sure of the best education officers being left to decide which pamphlets his men need most and then applying for them t some central depot.

Clearly the opening of the permanent home of the Army School of Education at Eltham Palace is symolic of the ambitious plans being formulated by the authorities in the War Office. In order that the projects envisaged may be assured of complete fruition, it would be as well to be sure that the machinery in the field is well oiled with enthusiasm among the education officers and sympathy and understanding from their seniors.

It seems therefore not only desirable but even essential that the main criteria in the choice of an army education officer should be academic qualifications in the principles and practice of adult education, the personal quality of leadership, and a background of educational experience and good record. We would place leadership as paramount among these. Military record and length of service should come very low in the scale of qualifications. We reiterate that the Army is not an academic institution; but where cultural, vocational and technical training is being practised, that training must rank high. It must not be treated with indifference or as of little importance, and all stumbling blocks must be removed. It is good in this connexion to read that at the courses to be held at Eltham Palace "Army Educational Corps officers are to be joined on various courses either by the unit education officers who are concerned with the fine details of the scheme in the units themselves, or by commanding officers who are responsible for seeing that good educational facilities are being provided for men and women under their command". At such courses, the main effort should be directed towards imbuing these officers with enthusiasm: they can easily be *ordered* to provide the facilities, but if they do so with an offhand lack of interest, condescendingly and with a show of indifference, then more harm than good will be done. For this great scheme to succeed, at any rate, in the field, young, enthusiastic and well-trained educationists are required; and their enthusiasm must be encouraged by the all-important sympathetic understanding and vigilance of their seniors.

ORIGIN OF UNIFORMITY

Social Learning and Imitation

By Neal E. Miller and John Dollard. (International Library of Sociology and Social Reconstruction.) Pp. x+284. (London: Kegan Paul and Co., Ltd., 1945.) 15*s.* net.

MOST past studies of learning have been concerned with the acquisition of intellectual or motor habits and skills. The learning process has been studied, so to speak, in a social vacuum. With the subject of imitation, text-books have usually dealt casually, explaining it in terms of current theory, nativistic, 'associationist' or, more rarely, in terms of learning. Familiar phenomena are the ones most liable to be lightly passed over, and it is perhaps just because imitation is so pervasive and universal a process that its significance has been overlooked.

In the present volume we meet the first serious attempt at an experimental approach to imitation. The authors take a new path. They expound the 'reinforcement' or 'reward' theory of learning as applied to (i) learning by imitation and (ii) learning to imitate. This theory is derived directly from the studies of Pavlov, Thorndike, and Watson which have recently been synthesized by Prof. Clark Hull in his "Principles of Behaviour". Unless the reader is conversant with Prof. Hull's work, there is much that he will fail to appreciate in the present volume.

The argument follows the so-called 'hypothetico-deductive' method employed in other publications of the Yale Institute of Human Relations. In theory, this means postulating a small number of plausible assumptions from which certain principles are deduced; experiments are then designed to test whether the principles are in accord with the facts. The actual plan adopted by the authors was as follows. First they familiarized themselves with applying learning theory to social and imitative behaviour, mainly of children in everyday life. A preliminary list of relevant variables was then drawn up which were manipulated in experiments. This led to a refinement of theory, which was applied to such topics as leadership, crowd behaviour, lynching, and diffusion of culture.

Four factors are singled out as operative in learning: drive, response, cue, and reward. All these must be present before learning can take place. 'Drive' means motivation; unless the subject is impelled to act, no learning can take place at all. Likewise, the 'responses' for the act of learning must form part of the psycho-physical equipment of the learner. 'Cues' are distinctive signs which elicit the correct responses. Finally, that response is learned which has been rewarded. Reward reinforces the response by reducing the drive.

The authors distinguish three kinds of imitative behaviour which they name (rather awkwardly) 'same', 'matched-dependent' and 'copying', respectively. In 'same' behaviour, two or more persons react identically (for example, buying tickets) in response to stimulation by the same cue. In 'matched-dependent' behaviour only the leader is able to read the relevant cues, the followers more or less blindly following suit (as in crowd formation); in 'copying', however, the copier knows when his response approximates to that of the leader or model (as in learning a new language). All three kinds of imitative behaviour conform to the same hierarchical conditions. In other words, they are all expressions of subordination to others, in respect of age, status, skill, or intelligence.

The experimental results illustrate various ways in which imitation generalizes. Thus if subjects are rewarded for copying one leader and not another, they will learn to imitate the first and not the second. Imitation spreads from one leader to another similar one, from one situation to a similar one, and from one motivation to another. This is a different way of saying that the prestige of leaders generalizes to other leaders, or to other situations or motivations. None of these results is startling, but all are in accord with common sense. The cumulative evidence indicates that imitation is learned and is controlled by the social conditions which reward it.

The chapters with the most compelling interest at the present time are those on crowd behaviour and lynching. By explaining these in terms of learning theory, they are integrated within experimental psychology. This applies to the effects of all the known factors influencing crowd-behaviour, including inter-stimulation, proximity, numbers, anonymity, prestige of leaders, repetition of stimuli, 'vicious-circular' reactions, emotionality, and uncriticalness. Nearly all these are exemplified in lynching.

The analysis of a lynching helps us to understand one of the pressing problems of to-day, namely, human potentialities for organized brutality on a mass scale. We have seen from the disclosures of the concentration camps that despite deeply rooted humane traditions, a considerable number of individuals who are not psychopaths can 'learn' to execute a programme of sadism with a callousness which challenges belief. In lynching we have a comparable phenomenon, though it is of brief duration and produced in conditions of mass excitement. Thousands of peaceful, law-abiding villagers behave collectively in a way which individually they would abhor. The striking feature which emerges from both 'horror' camps and lynching is this: variation in *potential* brutality is much narrower than in *actual* brutality. Beneath the skin we are much more alike than we appear to be on the surface. Moreover, beneath the smooth civilized exterior the primitive energies are still untamed. Thus it is easier for imitation to be learned and to spread rapidly in undisciplined emotional behaviour. Imitation reduces individuality of response and increases uniformity. If we are to have a stable and humane order, we must look to the 'models of prestige' which evoke widespread imitation.

This is not an easy book to read, and not simply because it makes severe demands on the reader's capacity to follow a series of intricate discussions. Often one has to read a paragraph several times, only to be rewarded by what seems to be a commonplace. It was the authors' professed aim to make their exposition at once rigorous and informative to the non-specialist. If they have discharged the first part of their task with distinction, they have not succeeded so well in the second part. It is to be regretted that with the exception of the last two or three chapters the style of the book will limit its appeal to the specialist.

JOHN COHEN.

IN SEARCH OF RIGOUR

The Foundation of Phenomenology

Edmund Husserl and the Quest for a Rigorous Science of Philosophy. By Prof. Marvin Farber. Pp. xi+585. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1943.) 33*s*. 6*d*. net.

FROM the University of Buffalo there is beginning to flow, as from a watershed, a determined stream of philosophical enterprise, likely, given time and circumstance, to gather momentum as it goes. Prof. Marvin Farber, in this book, the latest venture of the School of Philosophy and Phenomenological Research, has put scholars everywhere in his debt for a labour of love—for and on behalf of Edmund Husserl—difficult to value too highly. It should be said at once that the author is not prepared to accept all Husserl's doctrines without reserve, nor is the nexus of students with whom he is associated ready (as he wrote to me recently) to set up a patron saint in advance to preside over their deliberations. The position is in fact wholesomely fluid. Further, there is no attempt to erect German philosophy in general upon a pedestal: on the contrary, it is found to be unsatisfactory in a variety of ways. This may be due in part to a strife of schools, all too common in Europe, but luckily seldom encountered in the United States. All that is asked is that no hasty judgments should be passed upon such a complex theme as Husserl's pattern of thought. Indeed, to be irresponsible here would be more than ungracious.

So much for the background. We are now invited to contemplate Husserl as 'historically conditioned' the founder of a scientific outlook akin to a *philosophia perennis*, albeit at the same time pliable enough for progress. Additionally, he appears with all the fire and zeal of the Hebrew prophets, in sure and certain hope that his radicalism is well founded, his mission o mankind essential. In this he resembles our own McTaggart, who used to say that the study of philoophy is the most urgent task for every thinking person to tackle, for without it our deepest cravings remain unsatisfied.

In a work so erudite as that now under review, it is agreeable to be allowed occasional glimpses of the personalities of Husserl and of those chosen few to whom was given some measure of his friendship. As a help to the reader's understanding, too, these ntimacies are valuable, and are not to be taken nerely as light touches. For example, the wordportrait of Brentano, at once sacerdotal and learned, brings vividly before one the deep impression that his lectures must have made upon Husserl, and how he determined to forsake mathematics forthwith (in spite of having worked with Weierstrass) in quest of a truly rigorous philosophy.

Much of the text is of necessity devoted to critical surveys of such monumental works as the "Philosophy of Arithmetic", "Prolegomena to Pure Logic", and "Logical Investigations". Of these it is scarcely profitable to attempt an analysis here; preferable perhaps to select a few outstanding features of Husserl's work as a whole, and to discern his purpose. One such characteristic is his ability to make or discover distinctions. It is a major concern of the phenomenologist. Physically, it is akin to using an optical instrument of increased resolution rather than one of extreme magnification. The master's Freiburg period demonstrated this, when someone at his lectures remarked that to sit under him was to find 'new eyes' in philosophy. As a corollary, a warning hand is laid upon the artificial simplicity, so beloved of the superficial and the slick. Complexity rather than the reverse is to be expected: yet a foundation of experience is seldom lacking.

Again, Husserl seems to hark back to his earlier mathematical substratum in stressing the power of the conception of invariants. This now means much more than a method of dealing with transformations; it connotes the 'necessary general form' of all constructive thinking.

Of all the ways which Husserl follows in order to distil his purest thought, perhaps the most remarkable is the establishment of the *epoché* (ἐποχή). He proposes this in place of the universal doubt of Descartes. Thus the world is eliminated (*ausgeschaltet*); which done, transcendental consciousness remains as the phenomenological residuum. The act of so-called 'bracketing' is probably not exactly what the English mind is intended to understand by it. Rather we might think of such judgments as 'waived', since by this term is suggested the possibility of switching in again when the particular need for the process is over. Husserl would probably never have gone so far as to suggest that his eliminated quantities were entirely beyond recovery.

Time and again we find the philosopher in the evening of life returning to the fray, clarifying and deepening his message, yet never doubting that his system contained within itself the essentials of a pre-suppositionless structure, unrelenting in radicalism and veneration for rigour.

Husserl was not to escape some of the barbarities of the Third Reich. Declassed and ignored, he was nevertheless able to write "I prove *sub specie æterni* my right to live". F. Ian G. Rawlins.

COMPARISON OF ENZYME AND IMMUNE REACTIONS

Immuno-Catalysis

By Prof. M. G. Sevag. Pp. xv+272. (Springfield, Ill., and Baltimore, Md.: Charles C. Thomas; London: Baillière, Tindall and Cox, 1945.) 4.50 dollars.

NEAR the end of the nineteenth century, Ehrlich first directed attention to the similarity between enzyme and immune reactions on the basis of their highly specific character. "Immuno-Catalysis" examines this similarity in the light of modern work, and, further, puts forward a detailed case to support the view that the formation of a specific antibody in response to the introduction of a given antigen fulfils all the criteria of enzyme-catalysed systems, suggesting that antigen (catalyst) merely directs the formation from serum globulin (substrate) of antibody (product), which in the immune reaction acts as a specific enzyme inhibitor.

The work is divided into five parts entitled: Part 1, antigens as biocatalysts; part 2, antibody as a specific enzyme inhibitor; part 3, anti-enzyme immunity; part 4, immunity against bacterial enzymes; part 5, the problem of antibody formation against respiratory enzymes. Part 1, in attempting to decide upon the mechanism of antibody formation, necessarily deals with the chemical and physical properties of antibodies and their relation to the serum globulins, with the different theories of antibody formation, and makes some mention of the problem of serological specificity. It is shown that the available evidence favours the idea of the enzymatic action of antigen in stimulating antibody formation.

Part II is concerned, in detail, with the factor of specificity in immune and enzyme reactions, discussing the well-known work of Landsteiner, Avery and others using modified antigens, and with the analogy between enzyme inhibition and antigen-antibody association. Although Parts 1 and 2 contain a strong case for the antigen-catalysed formation of antibody and for the inhibitory action of antibody in the immune reaction, I feel that the case could in parts have been improved by the omission of some of the elementary material, for example, Section B of Part 1 dealing with simple types of chemical reaction, and by a more expanded treatment of the lesser known aspects of immunity, such as anti-antibodies.

Part 3 deals in detail with the question of anti-enzyme immunity, discussing the objections to the existence of anti-enzymes and the importance of non-specific adsorption of proteins, as well as the effect of pH change on enzyme – anti-enzyme combinations. The remainder of this part, and also Parts 4 and 5, form a collection of experimental data on the formation of antibodies and immunity against different enzyme systems. Although the critical analysis and presentation of all relevant experimental data is essential in establishing the nature of antibody formation and reactions, it is felt that this part of the work might well have been separated as an appendix from the main arguments which occur in the first half of the book.

The book is well supplied with references, has a good index (index and references occupying more than forty pages), and is well produced. It should be useful to specialists and non-specialists alike.

P. Johnson.

THE IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY

THE Imperial College of Science and Technology came into existence as the result of the federation of three colleges already established in South Kensington, namely, the Royal College of Science, the Royal School of Mines and the Central Technical College of the City and Guilds of London Institute. One of these, the Royal College of Science, and in particular its Chemistry Department, may be said to have originated in the Royal College of Chemistry which was opened in George Street, near Oxford Street, in October 1845 (see p. 524). Thus although the Imperial College of Science and Technology was not incorporated by royal charter until 1907, this year is appropriately regarded as the centenary of the College, and it was marked by a great gathering in the Albert Hall on October 26, attended by their Majesties the King and Queen, the Chancellor of the University of London (the Earl of Athlone), and the Vice-Chancellor (Prof. D. Hughes Parry).

Lord Rayleigh, chairman of the governing body of the Imperial College, surveyed briefly some of the activities of the College; his full address is printed elsewhere in this issue (p. 520). His Majesty the King, whose words were broadcast by the B.B.C., then spoke:

THE Queen and I have listened with special interest to the account which Lord Rayleigh has given of some aspects of the work of the Imperial College since its foundation. His position as a former professor and as chairman of the governing body qualify him to speak of this subject.

We have heard something of the way in which the College has carried out the intentions of those who shaped it. I speak now as its Visitor, and as its Visitor I recall the interest taken by my family, not only in the Imperial College since its foundation in the reign of King Edward VII, but in its three constituent colleges ever since the first beginnings which we celebrate this evening. The Royal College of Chemistry, at its inception in 1845, had as its president my great-grandfather, Prince Albert. He showed the same concern for the well-being of de la Beche's School of Mines, and as president of the Royal Commissioners for the Exhibition of 1851 he gained for science and the arts that great site on which, with other institutions, the Imperial College now stands.

It is, I think, now generally accepted that the idea of the great International Exhibition of 1851 was started by the Prince Consort personally, and that he took a large share in carrying it out. At the time, it had to face serious opposition in the Press, and while a Royal Commission took formal responsibility, the industrialists hung back and did not give the necessary support. The Prime Minister, Lord John Russell, had anxious consultations with his colleagues, and as a result it was arranged that Dr. Lyon Playfair should become a 'special commissioner'. The Prince had some slight acquaintance with Playfair and, before appointing him, means were found to improve it. Eventually the Exhibition was a financial success, and left a large surplus in the hands of the Commissioners, which they spent (mainly at the instance of the Prince and Dr. Playfair) in purchasing the South Kensington site.

Lyon Playfair, the Queen bids me remind you, bore the name of her family, with which he was connected through his mother, Margaret Lyon: and indeed his school holidays had been largely spent in the manse at the Queen's old home, Glamis Castle. As Lord Rayleigh remarked in passing, he heads the distinguished list of your professors of chemistry, having held that position in the Government School of Mines, prior to its incorporation with the Royal College of Chemistry.

But while it is interesting thus to recall the past, my own concern as your Visitor is with the Imperial College of to-day, and as your Visitor I take pleasure in the contributions it has made to total victory. Lord Rayleigh has touched on some in the fields of applied entomology and preventive medicine, and I am well aware that he could—had time allowed—have pointed to equally impressive victories won by your other departments in other fields. I know that the success of our D-day invasion was in great part due to engineers trained in your City and Guilds College, and I know, moreover, that Imperial College has contributed to victory not only by research but by its training of men who go from it to all parts of my Empire. Thus we have heard much, lately, of uranium; for rare materials such as this, no less than for commoner sources of power like coal and oil, the search goes on unceasingly throughout vast areas, and many of those who carry it out have received their training in the Royal School of Mines.

Justifiably we take pride in the achievements of British science and technology during these last years of total war. But with that pride is mingled apprehension, as we reflect on the ever-increasing power that science is giving to a world so prone to use power for evil ends. The atomic bomb, especially, gives food for sombre thinking: it greatly reduced the tol of human lives in the war now ended, but dare we hope that this new discovery will henceforth be controlled for the general weal? I say to you students here assembled—men and women who will soon be going out from Imperial College to your work in the world—on you and others of your generation rests a burden of responsibility greater than men of science have known before; not only to apply your knowledge and training to the service of mankind (that has been done, and well done, by generations that have preceded you), but so to act in the light of that knowledge and training that science may not again be used to destroy.

DR. R. V. SOUTHWELL, rector of the Imperial College, made the following reply:

It falls to me to render to Your Majesty—speaking both for staff and students—most hearty thanks that you, our Visitor, have been pleased to grace this celebration with your royal presence. That Her Majesty has been pleased to accompany you completes our happiness—and gives, perhaps, especial gratification to women members of a college in which, though at all times outnumbered, they have never seen themselves as a 'forlorn hope'. Thrice within living memory we have had proof of royal interest in the growth of our constituent colleges: never before have we been favoured with the presence both of our King and Queen.

To deserve that interest and favour has been and will be our aim. Your Majesty has spoken of our history, and of famous men that we delight to praise: though that history is short by English standards, it is a history of which we think we may be proud, and we believe that its last six years—when their story can be told—will not be judged unworthy of the years that have gone before; and because we think our College has contributed not unworthily to victory in war, we are hopeful that in years to come it will further no less worthily the ends of peace. Your Majesty is served with equal loyalty in diverse ways: our best service, as we believe, will be to spend our energies in promoting science and technology by study, teaching and research.

I have not thought it would be your pleasure to hear from me the tangled story of our evolution. Reviews that aim to be exhaustive are apt as well to be exhausting, and I would beg leave now for only one remark. It is a happy feature of that story that it starts from an act of Your Majesty's great-grandfather; its second chapter now begins with this mark of Your Majesty's favour. It was the Prince Consort who in 1845 presided over the council of that College of Chemistry from which, by a line occasionally devious, the Imperial College traces its descent; it was by his personal intervention that von Hofmann was secured to be its first professor; and it was he who in 1846 laid the first stone of its new building in Oxford Street: a stone that lies here, waiting to be again embodied in our chemistry buildings. It was his unsparing effort that ensured success for the Exhibition of 1851, and thereby the means of realizing his own far-sighted vision of a great metropolitan centre for the promotion of the sciences and arts. No college owes more to its founder than ours to him.

Had his wide views been general, our problems now would be less hard; for then on his splendid ground-site, buildings would have risen in ordered sequence, and Imperial College, chartered in 1907, would have been a federation of colleges that not only were adjacent in the fields of science but lay within the same London borough. As has turned out, though two have buildings that adjoin to form a well-placed whole (and here I would recall that the first stone of each was laid by Your Majesty's grandfather, as Prince of Wales in 1884 and in 1909 as King Edward VII), the third—our Royal College of Science—has its departments scattered widely. It is our hope that not many years will pass before it too has buildings that conform with an ordered plan; but the time has still to come, and as yet we have no place where we may beg Your Majesty to lay this stone, that it may rest from its wanderings. Yet we have craved that some record may remain within our College—to be seen by those that will come after—of Your Majesty's presence with us here; and to that end we have started to prepare a book, to tell of our College's origins, of its evolution in the hundred years now ended, and of what was done to mark this first centenary. It will tell as well of the appeal that we have made in recent months for funds wherewith to foster, in the future, a fuller and more corporate college life; and it will record the names of donors who have responded. We would beg Your Majesty to append your name to this record as our Visitor, so that men of our College may read, in years to come, of the signal favour shown to us this evening: favour for which all we who are here assembled tender to Your Majesties our humble and hearty thanks.

WE print below some tributes to the influence of the Imperial College, which we have received from distinguished senior members of the College:

SIR RICHARD GREGORY, BT., F.R.S., Editor of *Nature*, 1919–39:

When I went to South Kensington in 1886 it was as a 'science teacher in training' at the Normal School of Science, now the Huxley Building of the Royal College of Science. As the original name signifies, the school was a place for the practical training of teachers in elementary science, so that they could conduct courses of instruction in day and evening classes under the Science and Art Department. In physics, the first year's work consisted almost entirely in the making of apparatus, from thermometers to galvanometers, with the necessary linear or angular graduations for measurements with them.

To those of us who intended to become science teachers, this course was admirably suited; for in those days few ready-made physical instruments were available in any schools. Vernon Boys, who was in charge of the physical laboratories, was thus able to impress upon hundreds of students the value of making use of the simplest materials in the art of experimentation, of which he was an acknowledged master throughout his life.

This was also the spirit of the completed course of physics (Parts II and III) which I took with Prof. Boys, while he was producing the extremely fine quartz fibres for use in physical instruments. Its purpose was not so much to load the mind with facts as to stimulate independence in methods of scientific research. While I was taking the advanced course, Prof. (afterwards Sir Arthur) Rücker was appointed to the chair of physics at the College, and it was he who began the developments of the subject to the high university standard in teaching and research for which the College is now world-renowned.

As one of the oldest students of the original Normal School of Science, I welcome this opportunity of paying grateful tribute for what it did to give us sound ideas on scientific methods and meanings. We were justly proud of the school in those days of Victorian science and were given additional honour when it became the Royal College of Science, and later a constituent part of the Imperial College of Science and Technology.

After my student days, my direct association with the teaching of research was as an assistant to Sir Norman Lockyer in the Department of Astronomical

Physics and the Solar Physics Observatory. This determined my whole career, for in 1893 I became Sir Norman's assistant on the staff of *Nature* and succeeded him as Editor in 1919. With these early recollections in mind, and knowing the high scientific standing of the members of the staff of the Imperial College since my days, it would be almost a presumption for me to add my testimony to its greatness. I shall, however, always cherish in my heart the influence the College has had on my life, and entertain with pride the feeling that I once played a minor part in the work of a branch of this great centre of scientific learning and research.

Dr. W. H. Eccles, F.R.S., formerly professor of applied physics and electrical engineering, City and Guilds of London Technical College:

In the closing years of the nineteenth century, when I was admitted to the Royal College of Science, I found it a well-established and bustling community. Nearly all my fellow-students seemed to be remarkably mature and responsible beings who had already had experience in science-teaching, in works or in laboratories. They, rather than the staff, created the atmosphere of the College, which might be described as one of altruistic utilitarianism; many of them were reading science in order to assist industrial progress, each in his original walk of life. Moreover, the wise men who had made the College syllabuses had fostered this atmosphere in advance by ensuring that the instruction should be on a Baconian not a Platonic basis.

Active discussion with one's fellow-students showed that this strong orientation toward usefulness intensified the desire to read 'pure' science, a desire which merely gave expression to the spreading opinion that the important changes in industry would henceforth come from accurate measurement and the scientific method rather than from the method of the craftsman, and that new processes and even new industries could spring only from new scientific discoveries. Men like Armstrong, Judd, Huxley and Magnus had been preaching this doctrine for some twenty years, and had aided in setting up at South Kensington not only the Royal College of Science, but also the School of Mines and the Central Technical College of the City and Guilds of London Institute, all of which are now components of the Imperial College.

The gratitude I feel for my five years of opportunity at the Royal College of Science (plus occasional lectures at the Central) is deepened by the assessment I obtained there of the functions of science in the modern world. A new and broader meaning was given to the word 'technology' which, according to the dictionary, is the 'science of the industrial arts', but which now appeared to be 'science *for* the industrial arts, existing and to come'. If only there had been at the Royal College of Science research courses in the application of modern science to problems in nascent industries, I should have departed even more indebted to the College; as it was, I became one of Marconi's assistants and was launched on the practical world in that way.

Looking back at the careers of my contemporaries at the College, I find that nearly all of them took up the task of introducing science, in one way or another, into industrial affairs; I know of many who have done much for industry. May the modern Imperial College be increasingly successful in moulding such pioneers.

Sir William Jarratt, formerly Comptroller-General of Patents, Designs and Trade Marks:

It is an appreciated privilege to be allowed to join the chorus of congratulations on the Imperial College centenary celebrations. During the years 1887–90, when I was a student at the College, the changes that were occurring included the amendment of the name and status of the Normal School of Science to the Royal College of Science, and I well remember my delight that my leaving certificate was signed by that great controversialist Huxley, the dean of the School and College, and by the founder and first editor of *Nature*, Sir Norman Lockyer, better known to readers of *Punch* as 'Noman Luckier'.

In those years research posts, either in industry or at universities, were not plentiful, and in consequence many students became science masters or took posts in the Civil Service such as Patent Office examinerships. With Government encouragement, however, the importance of research became increasingly recognized, and more students availed themselves of the opportunities to follow up scientific research. It is a matter for congratulation that during this development the College authorities have never ceased to recognize that side by side with scientific research, long-term or otherwise, the industrial development and the social conditions of Britain necessitate the application of the results of research, and that this industrial application is stimulated by a strong patent law such as we fortunately possess. The best results from scientific research can scarcely accrue to the State without some such form of guarantee to those enterprising industrialists who take financial risks in applying to industry the results of research.

As the years have passed it has been a pleasure to watch the steady development of the College and its increasing influence among the forces that have retained for Great Britain its position in the forefront of scientific progress. I desire to congratulate heartily the College authorities on their magnificent record.

CONTRIBUTIONS OF THE IMPERIAL COLLEGE TO THE CONQUEST OF DISEASE*

By the Right Hon. Lord RAYLEIGH, F.R.S.

On an occasion like this it is natural to take stock of the work we and our predecessors have been able to accomplish since the first beginnings of the College a hundred years ago. But this work covers so wide a range, and so many different specialities in all branches, from physics and engineering on one side to zoology on the other, that in the course of a short address one cannot even glance at all aspects of it. Looking for some fairly comprehensive topic to which a good many of our departments had contributed, I was struck by the victories which had been won over the agencies of disease. It might appear at first sight that this was a matter of medical science, with the obvious comment that none of our departments deals with that subject. Important though the medical applications are, these investigations have been developed rather from the point of view of physics and chemistry. But there is no need to emphasize professional aspects of this kind.

---

* Introductory address for the Centenary Celebrations on October 25.

These problems are so vital to all of us that we must use any and every method to solve them, and accept help from any quarter. The civil engineer would at one time have said that entomology had nothing to do with him. Nevertheless, he was defeated in the attempt to make the Panama Canal until he had accepted the help of the entomologist in dealing with yellow fever, and the mosquitoes that transmit it.

Our efforts have recently been concentrated on overcoming our human enemies. Formidable though these have been, there is another class of enemies whose methods are very different, but whose fundamental purpose is for the most part the same, namely, to promote their own well-being at the expense of ours. They are to be found among certain of the lower forms of life, the microbes, which are primarily responsible for fevers and infection, and the insect bearers of disease, which play an equally important if not quite so insidious a part in conveying the microbes to the scene of action. It is only in modern times that these enemies have been recognized as such: and even now many people talk glibly about microbes with little or no understanding of how we have learnt that they are of the essence of disease, that they are in the food we eat, the water that we drink, and the air we breathe. Not only are the lower forms of life constantly lying in wait to attack life and health, but they are also formidable competitors for our food supply, and can rarely be altogether prevented from taking their toll of it.

The late Sir Alfred Keogh, director and reorganizer of the Army Medical Service, and afterwards rector of the Imperial College, told me an incident which may serve to illustrate this. The scene was the Army Council, of which he was, of course, the only medical member. He urged the introduction of certain hygienic measures, explaining briefly the reasons for them. Not much was said by his more purely military colleagues, but one of them, a general who had distinguished himself greatly in the South African War, came up to him afterwards and said: "I was very glad to support you in what you wanted done; but, tell me as man to man, do you really believe in microbes?" Keogh, rather at a loss for words, could only insist on his coming to see them for himself.

I will now try to sketch in outline how this belief gradually forced itself on the scientific world, illustrating the story as far as possible by the investigations made in the Imperial College.

It had become widely recognized that the spread and multiplication of fever cases had many points of resemblance to the spread and multiplication of living beings. Thus each species of plants or animals multiplied according to its own kind; and fever cases did the same. Smallpox gave rise to smallpox and to nothing else; typhoid fever gave rise to typhoid fever and to nothing else. The infection starting from a single case could give rise to an unlimited number of others, and putrefaction was one single phenomenon, whether it occurred in the wounds of the living, or in dead bodies of men or animals.

On the other hand, observation seemed to show that exposure to the air was the essential condition for putrefaction. For meat broth, boiled to expel air and sealed up in glass flasks, would remain clear and free from putrefaction for an indefinite period. If the sealed flask was opened to admit air, putrefaction quickly set in. The same thing is now familiar to everyone in cans of tinned meat. This remains good indefinitely until it is opened and the air is admitted. These contrasting facts appeared to Tyndall's generation very contradictory. There appeared to be no doubt that putrefying animal matter was swarming with life, for it could be observed under the microscope that this was the case; and since there was no obvious source for this life to have come from, many were of opinion that it must have been generated in the putrefying matter. This question was, in fact, whether there was spontaneous generation of life or not. No question could be of greater importance. It was urged by some that since life existed on the earth, it must have come into existence since the earth was formed; and if this had happened once, it was reasonable and in accordance with the scientific habit of mind to assume that it would happen again in similar circumstances: and they thought it obviously did happen under observation when meat became putrid. Tyndall, however, was not satisfied by this reasoning; and I will try to give an account of his contribution to the subject.

In his researches on radiant heat, and in his experimental lectures at the Royal Institution and at this College, he had been in the habit of making use of the electric arc to throw out a concentrated beam of light, and he observed how the track of the beam could be traced by the way in which it illuminated the dust particles in the air. Most of us are now pretty familiar with this, because of the searchlights used in war. It was not so commonplace then, and I may recall that the only source of current for the electric arc, or at any rate, the source in general use, was a primary battery of forty or fifty Grove cells, very tedious and troublesome to set up and maintain. Tyndall tried whether he could not get rid of the dust in air. He found this difficult at first, but ultimately succeeded by filtering the air through tightly packed cotton-wool. When he did this, he found that the track of the beam became invisible, and the air through which it passed was, as he expressed it, optically empty.

He prepared specimens of broth from various kinds of meat and fish, and boiled them in order to kill any living matter they might contain. Then he found that such broths would putrefy when they were exposed to ordinary air, but not when they were exposed to air which had been freed from dust, and which showed no motes in a concentrated beam of light. Ordinary air caused putrefaction. Dust-free air did not. These simple tests went far to resolve a great and fundamental question. The putrid broth which had been exposed to the open air was soon found to be swarming with living matter, visible as such under the microscope. Where did it come from in the first instance? Was it generated in the liquid? That was the opinion of one prominent school of thought; but Tyndall's experiment showed that if all living matter was killed by boiling, exposure to the air would not generate any more. Life only comes from life, and however much appearances may at first sight suggest the contrary, it is not generated anew under our eyes.

Tyndall's researches ran to a great extent parallel with the famous investigations of Pasteur, with whom he was in touch. Without prejudice to workers elsewhere, we on the present occasion naturally dwell on the contribution of our professor, made by a method entirely his own, which led him to important discoveries in other directions also; for example, the artificial imitation of the blue sky, and its optical peculiarities—far enough, one might think, from problems of infection, disease and the origin of life.

Bacteria are not only very small, but also they are colourless, and it is only after they have been stained that it becomes reasonably easy to investigate or even see them. It is found that one class of bacteria will take up one class of stain, exemplified by methyl violet, and other bacteria will take up a different class of stain, exemplified by fuchsin, which is red. The reason for this is somewhat obscure, but whatever the reason, the fact is very helpful in distinguishing between the various bacteria. I have entered on this subject because I wished to recall that the aniline dyes used for this purpose, and also for such minor purposes as colouring our clothes, carpets, curtains, cushions, had their origin in this College in 1856, when W. H. Perkin discovered mauve. He was not a professor, but a student under Hofmann, and was only eighteen years old. He immediately took the matter up commercially, though Hofmann did not encourage this, and Perkin himself had never even been inside a chemical factory before. It sounds like a fairy tale, but he made a fortune out of it, and retired to pursue his studies in pure science.

I have mentioned methyl violet and fuchsin. These were among the discoveries of A. W. Hofmann, who succeeded Playfair as professor and by whom Perkin was trained. It may be a little confusing to be told that the first aniline dye was discovered by the youthful pupil and the later ones by the professor, but so it was.

The famous name of Hofmann, who was brought here by the personal influence of the Prince Consort, leads to another aspect of our main topic. Much anxiety had been caused in the early sixties of the last century by the questions of the purity of water supply and of the disposal of sewage. Pure water in great cities is now almost taken for granted. This has not always been so. When Catherine of Aragon came to England as a bride, she was warned not to drink water in England as it was not fit to drink, and as regards the low-lying land of the southern counties this was doubtless quite true. Coming to a much later period, I can remember, probably about 1885, when I made as if to help myself to a glass of water in the waiting room at Liverpool Street Station, that I was warned never to drink water in such places! The warning may have been somewhat out of date, but not by much, for surface wells were still in use in some parts of central London as late as 1867, when the water from them was found on analysis to be disgustingly polluted, and quite unfit for human consumption.

Hofmann first gave attention to the subject of water analysis at the same time that he was at work on the aniline dyes, but he had scarcely got his teeth into the problem before he left Britain for good and was succeeded in his professorship at the College by Sir Edward Frankland, who took up the question with great vigour, and examined anew for himself the various methods of analysis which had been in use, with the result that he found that on some of them, at least, little reliance could be placed.

I ought to explain more clearly what is meant by water analysis in this connexion. We are not, of course, speaking of mineral or medicinal water but merely of drinking water; and the vital question is, Has it been contaminated by contact with foul matter? Very little definite was known about micro-organisms at that time. But Frankland already considered it more than probable from the history of past outbreaks of typhoid fever in various places that the infection could be carried by drinking water, and that a specific poison associated with this disease must exist. For bad though the position was, it was only exceptional specimens of foul water that gave typhoid fever, so that foulness was not enough by itself. No one, however, knew at that time what this agent was, or how to test for its presence; and indeed, we have no very practicable direct test of this kind even now, though we understand a great deal more about what the source of mischief is and how to guard against it.

In the absence of a direct and easy test as to whether the water is actually infected, we have to fall back on indirect tests as to whether it has been exposed to contamination, and these are found in seeing how far the water contains ammonia and nitrates. These substances are harmless enough in themselves, but they contain nitrogen, and as Frankland proved in detail, it is usually pretty certain that they got their nitrogen from highly undesirable sources. So an analysis for these tells us a great deal as to whether the water can be trusted.

Having established these and other methods, he put them extensively into practice, and examined the water in London and in various parts of England. The result was broadly to confirm that there was a very great difference between surface water from the Thames and Lee Valley for example, and that from deep wells sunk in the chalk or the greensand. The test of analysis on the lines explained showed that the shallow-well water in the Thames Valley, though it might look and taste quite good, was really little better than filtered sewage.

The idea prevails rather widely that we can readily decide whether a sample of drinking water is safe by looking for the presence of typhoid bacilli. Unfortunately, to look for the typhoid bacillus in drinking water is like looking for a needle in a haystack. It might succeed in the case of extreme contamination, but it is not easy enough or certain enough to be a practical procedure. Bacteriological examination is of the greatest value, but like the chemical methods it only leads to general conclusions, and by no means supersedes those methods.

The development of our knowledge of bacteria is by far the greatest contribution ever made to the study and prevention of disease; for it has given us not only the modern mastery of infectious diseases, but also has made possible the great advances in surgery. I have tried to bring home to you that our College has had its fair share in their development. But we must now turn to another subject, kindred to this one, and of comparable importance. That is the control of insect pests.

Man flatters himself that he is the 'Lord of Creation'; but the insects do not show themselves impressed with this point of view, and usually go on their own way, hostile to man, and treating his pretensions with very little respect. It has always been known that some species, such as the scorpion and the tarantula spider, might on occasion be dangerous but it is only in comparatively recent times that we have understood how many and how formidable are our enemies in the insect world.

The man of science feels intuitively that definite facts about Nature always have their value, but he does not always find it easy to convince the man in the street of this. If there was any branch of science where it appeared difficult, it was perhaps in entomology. The insect pests are our enemies in innumerable ways. We have only just begun serious warfare against them, and the successes which have been won in the last few decades are but a fraction of those that may fairly be expected in the decades to come; moreover, our victories over them have a permanence and finality that cannot be hoped for in victories over human enemies. The great strength of our insect enemies has been that for long we did not understand that they were our enemies at all. That lesson once learnt is not likely ever to be forgotten while our civilization endures. But it was not learnt easily. The critics who make merry at the expense of scientific pursuits have seldom been more confident or more utterly wrong than in this instance. For example, Thomas Shadwell, a well-known playwright, published in 1676 a play called "The Virtuoso", in which he satirized the naturalist of the day as Sir Nicholas Gimcrack, whom he described as follows: "A coxcomb, he has studied these twenty years about the nature of lice, spiders, and insects . . . no man upon the face of the earth is so well seen in the nature of ants, flies, humble bees, earwigs, hoglice, maggots, mites in cheese, tadpoles, newts, spiders, and all the products of the sun by equivocal generation. This foolish virtuoso does not consider that one bricklayer is worth forty philosophers".

We know now that malaria is transmitted by anopheline mosquitoes, dysentery by the common house-fly, typhus by the louse and plague by fleas. The case of mosquitoes and malaria is of special interest, because it is not just any mosquito but the particular species of anopheles which is recognizable by 'walking on its head'. The recognition of facts like these is in the process of conquering the tropics for civilization, and I think we may fairly claim that it has been proved that if anyone is a 'coxcomb' it is not the naturalists who concern themselves with these insects, but the critics who affect to despise them for doing so. I do not say this in any spirit of self-complacency, having myself, many years ago, been unsympathetic to a friend who concerned himself with the close study of fleas infecting various animal species.

In view of facts like those I have mentioned, the Zoology Department of the College under Prof. J. W. Munro has, of recent years, paid special attention to the subject of economic entomology, and has built up a large body of knowledge about insect pests and how to combat them; and when the War came its staff and resources have been used to the full in protecting stocks of grain from insects and rats, and in combating the mosquitoes, flies, and other even less pleasant insects which infect our troops with malaria, yellow fever, sleeping sickness, typhus and plague.

Typhus, there is good reason to believe, killed more people than all the weapons of war during 1914–18. We can scarcely say as yet whether a similar statement would hold for the present War; but most people find it difficult to realize the true bearing of facts of this kind. Many, it may be suspected, picture the horrors of war mainly in terms of bayonet charges and the like, as in the pictures of Napoleon's campaigns; and, indeed, these are arresting enough: but they only show a minor aspect of the terrible reality. The louse, we now know, is far more deadly than the bayonet.

The successful attack on insect pests has, however, depended to a great extent on the possession of a suitable insecticide to use against them. Supplies of pyrethrum were largely cut off by the entry of Japan into the War, and attention was turned to a new insecticide, D.D.T. Neither this substance itself nor the application as an insecticide is entirely new, but its value has been explored much more fully than before, and it has been used on an unprecedented scale. It is practically without smell, and is very persistent. Thus, when sprayed on walls at a suitable concentration it kills any fly alighting on them up to a period of three weeks. A bed sprayed with it is fatal to bed bugs for three hundred days, and clothing dusted with it is safe from lice for a month, even after several launderings. Impressive though these results are, it is not claimed that D.D.T. is a final solution of all insecticide problems or that it puts all other insecticides out of court.

As we have seen, the insect pests in many cases convey dangerous or deadly infection by their bite, and as we have seen, much is being done to cut off the sources of infection as well as to destroy its insect conveyors. It cannot, however, be claimed that full success has yet been attained in either direction, supposing that the invader has got past our defences, and has effected a lodgment in the human body. Can we still hope to attack him? Obviously this is a much more difficult matter, and for long it appeared almost hopeless. We can attack micro-organisms or insect enemies with all sorts of more or less poisonous disinfectants such as carbolic acid or D.D.T. when they are outside the human body, but when they have effected a lodgment inside it their position becomes far stronger; for we cannot in general attack the enemy without endangering the friend in whose body he has ensconced himself. You see, then, how difficult the problem is. Light has come from the recent development of penicillin, which while harmless to the patient is poisonous to the invading micro-organisms. Penicillin is the product of a plant mould, and the romantic circumstance is that nearly all the penicillin in use, which is saving lives and relieving anxious hearts all over the world, is the progeny of the single small spot of penicillin mould originally observed by Sir Alexander Fleming. The preparation of concentrated penicillin from it is a matter of no small technical difficulty, and with this and the question of its chemical nature our Organic Chemistry Department under Prof. I. M. Heilbron is vigorously occupied. But our hopes go much further than this. Penicillin is obtained at present from the natural plant source, just as, for example, indigo and a host of other economic products were obtained from plant sources. There is, of course, the difference that indigo is grown in the fields, while penicillin is grown in bottles. But indigo is now made in the chemical factory instead of being obtained from the plant, and the hope is that penicillin may also be produced synthetically, and much more easily and cheaply than now.

Before we try to build up the structure of the penicillin molecule we must, in the first place, have an accurate knowledge of its ultimate composition. That is to say, we must know what kind of atoms, and how many of each, go to build up the structure. That step has now been achieved, but it is by no means enough in itself. To picture what a house is like it is not enough to know what quantities of bricks, slates, timber and so on have been used in building it. You must know how they are arranged. You want an architect's plan. That is what we are trying to make for the penicillin molecule. When the elucidation of the plan of the penicillin molecule made by Nature in the plant has been completed, it will in all probability be possible to build up the same structure in the laboratory by the methods of synthetic chemistry, and even to go further by modifying the structure so as to extend its applicability.

THE ROYAL COLLEGE OF CHEMISTRY

By Dr. E. FRANKLAND ARMSTRONG, F.R.S.

THE centenary of the founding of the Royal College of Chemistry in October 1845 is an occasion on which we may well take stock of its influence on the progress of pure and applied chemistry in Britain.

The story of the hundred years is a story of men and not of laboratories—of professors and disciples, of enthusiasm and of hard work for its own sake. Laboratories are never large enough or sufficiently equipped—perhaps in Britain they never will be—but the great man rises superior to his physical surroundings or handicaps and the student is surely all the better fitted to face the future when not pampered. Latent powers are best evoked by sufficient severity of circumstances, as the long history of our race bears abundant testimony.

In the 1840's things were changing; a nation of countrymen was slowly turning into a nation of townsmen. It was an age of movement, of traffic on canals faster than the coaches on the roads, and on steam railways faster still. It was an age of wheels, wheels at the pit head, spindles in the cotton and woollen mills. The pace of life was quickening on every side.

In 1842 all England was agog: that great man Baron von Liebig was on tour in the industrial Midlands and North. The tour was personally conducted by none other than Lyon Playfair, who took care that Liebig should meet the most influential people and impress on them the national importance of the new science of experimental chemistry. Such a triumphal tour made its influence felt in all the chief centres of Great Britain. At the end of his visit, Liebig is reported to have said "England is not the land of Science"; a hundred years later there is still very much to be done before we can claim to be entirely free from this reproach.

Liebig's tour helped to direct attention to chemistry and make it a popular science, for it must be remembered that at this time it was very seldom that any students desired to become chemists. The Pharmaceutical Society claims that the first laboratory open to students was one under its auspices with Fownes as teacher. This would be in the early '40's, and he was the author of a text-book "Fownes' Chemistry". Jacob Bell, the then president, would have made the pharmacy into an *Apotheke*—not a druggist or a fancy goods store—had he been listened to. There were already courses at University College and King's College, London, in which chemistry was taught as part of the training for other professions. The promoters of the Royal College of Chemistry sought, however, to do something new by founding an institute in which chemistry would be studied for its own sake apart from professional requirements. It was anticipated that the students who came there would make chemistry the occupation of their lives and enlarge its boundaries by research in the laboratory.

The first effort of the enthusiasts, inspired by Liebig's visit, was to attempt to found a Davy College of Practical Chemistry within the Royal Institution. This effort did not succeed, but it led to further meetings and so the Royal College came into being. Two men share the credit for its foundation, Sir James Clark, the Queen's physician, and the Prince Consort. The Prince Consort was at that time president of the Society of Arts, in the affairs of which he took an active part, often presiding at council meetings. His contact there with men of science must have supplemented his personal interest in these matters and he was eager to lead the nation to take science seriously. But a new college of this kind could not have been created unless there had been a strong popular feeling in its favour. All depended now on securing the right leader. The advice of Liebig was sought; Fresenius and Will both refused, Hofmann was dubious about accepting, as failure of the new college would retard his career in Germany. Once again the Prince Consort intervened, and it was thanks to his efforts that Hofmann was given two years leave of absence from Bonn so that he might, if necessary, at once re-enter on his career in Germany. The choice was a happier one than anyone knew. Hofmann became not only the greatest research leader of his day; he evinced many other attributes which contributed to the success of the new enterprise.

Hofmann made a start in the temporary laboratories at George Street, Hanover Square, in October 1845. A year later it was possible to commence work in the new building in Oxford Street backing on Hanover Square. There were twenty-six students in the first course, among them E. C. Nicholson, F. A. Abel and, above all, Warren de la Rue, who more than anyone else helped Hofmann. Others were Henry How, Thomas Rowney, C. L. Bloxam, Robert Galloway.

The second batch of students brought thirty-seven more, including C. B. Mansfield and George Merck, F. Field, H. M. Noad, Bransby Cooper and John Blythe. It is to be noted that Hofmann's rising fame soon attracted his own countrymen to his laboratory, particularly as his private assistants, who included Peter Griess, the discoverer of the diazo reaction, and Martius. Other distinguished names of this early period were Crookes, Spiller, Tookey, Reginald Morley, Groves, Ansell, Church, Matthew Johnson, H. M. Witt, H. McLeod, Valentin, Barrett, Bassett, Vacher, O'Sullivan and Reynolds.

From its earliest beginning the duty of the College has been to produce men, leaders in their chosen walk in life. The professors, by their example, precept and teaching, encouraged a progeny keen on enlarging the boundaries of knowledge, able in their turn to teach and inspire a later generation. Science for its own sake, unfettered and unrestricted, must still be the keynote of its activities, even though to-day science has its practical applications to the daily avocations and health of the people and in the development and progress of industry. Unfortunately, the nation at large is barely science conscious, and it will remain indifferent until science, particularly scientific method, is more widely taught in the schools.

In 1851 the Government School of Mines and of Science Applied to the Arts was founded in Jermyn Street, with Playfair as its professor of chemistry. Some confusion exists about Playfair's post, which need not be discussed here. He retired in favour of Hofmann when the two colleges were incorporated in 1853 as the Metropolitan School of Science Applied to Mining and the Arts, which in 1863 had its name changed to the Royal School of Mines. In spite of the official incorporation, the Royal College maintained some measure of independent existence and ontinued to confer its own diploma until it moved to South Kensington in 1872, where it became part of he Normal School of Science in 1881. At the same ime the departments of biology, physics and applied nechanics went there from Jermyn Street. The uilding in which they were all housed became known ater as the Huxley Building.

In the wake of the 1851 Exhibition, and fostered y the newly created Department of Science and Art, a demand spread throughout Britain for instruction in science subjects—given mainly if not almost ntirely in evening classes—among which chemistry vas predominant, physics, botany and geology also ttracting many students. These classes, promoted or recognized by the Department of Science and Art, vere financed largely during many years by payments ased on the success of the students in its examinaions. To meet this demand for more advanced nstruction, yearly a number of selected junior eachers of, and promising students from, recognized lasses received free education and maintenance in he College after its removal to South Kensington in 1872.

In 1881 the name of the college was changed to the Normal School of Science, and in 1890 to the Royal College of Science, to mark enlargement and consolidaion of its scope and functions—among which from ts earliest days was a special reference to the applicaions of chemistry to "the Arts and Manufactures". Its students could be classified under the headings : ee-paying, exhibitioners ; teachers in training Science and Art Department) ; and, between c. 1886 nd 1902, Inland Revenue and Excise (customs) officers taking either the one- or the two-year course in hemistry. The academic year was divided into two nd not three terms and in each term only one subect was studied ; chemistry, with some mathematics, eing taken by all associateship students in their irst term as the initial subject of their course.

Hofmann resigned and went to Berlin in 1865 ; e was succeeded by Edward Frankland. Edward Thorpe succeeded Frankland in 1885 and five years ater the title Royal College of Science was born. William Tilden followed Thorpe in 1894. Frankland eceived the K.C.B. ; Thorpe and Tilden were knighted n recognition of their services to chemistry.

The changes of name of the College are somewhat ewildering. In fact, for some thirty years, during 851–81, there was a conflict of divergent aims and nterests between the party led by Huxley and the cience and Art Department, which wanted a great etropolitan school embracing all branches of applied cience, and the mining school opposition which did ot want to see the development of the Jermyn Street school hampered. It was in reality a conflict ver lack of space, a basic trouble which will always e true of a growing college.

On the foundation so truly laid by the Prince Conort, the edifice built by Hofmann has endured a undred years. Founded in days when chemistry ould scarcely be called a science, no fairy tale can atch the wonders of the progress of chemistry and f the dye industry which it is the proud boast of the ollege to have originated. The torch borne in turn y Hofmann, Frankland, Armstrong, Thorpe, Tilden, app, Wynne, Morgan and so many more still burns s brightly. The laboratories of the Royal College ave sent out into the world men who have given us lean water, dyestuffs, and brought progress to every ranch of pure and applied chemistry. Those who have taught have handed the ideals on to their students, who have in time permeated to every university in the land. A genealogical tree to-day would show few chemists who do not claim descent in some way from Hofmann or one of his three successors.

Although the first discovery of benzene is properly attributed to Faraday, it was Hofmann who, needing aniline, the key substance of the dyestuff industry, for his researches and hampered by the very small yield obtainable from indigo by distillation with alkali, discovered in 1845 how to convert benzene into nitrobenzene and reduce this readily to aniline. To-day we should still regard this as the most important reaction in organic chemistry. Thereupon Mansfield was set to work on benzene in the Oxford Street laboratory, and not only separated it from coal tar and showed how it could be prepared on the large scale, but also emphasized that it could be procured to any extent from this hitherto waste product.

Very soon afterwards, the aniline colour industry came into existence with Perkin's discovery of mauve in 1856, followed soon by an anthracene industry and an azo colour industry. Synthetic dyestuffs had arrived. All these centred around the College of Chemistry—the men who made them possible were Hofmann, Perkin, Griess, Nicholson, Simpson, Maule. Hofmann did his best to raise up an English tree of organic chemical industry, and for a while it grew apace. He was perhaps the first to urge that while capital can do much, capital directed by the lights of science may accomplish much more.

One of Hofmann's talents was his faculty of gauging the powers and special qualifications of those who studied under him. All who worked with him were stirred to enthusiasm, and failure to produce results was a real personal grievance. My father has written that "he made the student his personal instrument —no one has ever been more avaricious of results and he was always carried forward by this desire". Frankland, who succeeded him, had no such tendency ; he had peculiar difficulty in getting behind the students' work and finding out what had been done. Only those could work effectively with Frankland who needed little, if any, guidance. He let his students handle things for themselves and so gain an intuitive understanding of the method of discovery. His manner of lecturing was the very antithesis of Hofmann's, but his lectures were more impressive on account of the wealth of fact and the attention he gave to the experimental side. He was both a pioneer of research and of structural formulæ, and undoubtedly England's greatest chemist of his time.

In 1868 Frankland became a member of the Royal Commission appointed to inquire into the pollution of rivers and the domestic water supply of Great Britain. More than anyone else, he is responsible for giving us pure drinkable water, since he discovered that slow percolation through porous soil effected the oxidation and destruction of organic matter with great rapidity. His most famous pupil was H. E. Armstrong, who went to the College in Oxford Street just as Hofmann was leaving. Armstrong had two years and a term there, the last year or more being spent in the private laboratory working on the revision of the methods of water analysis.

Armstrong left Frankland late in 1867 to work for two and a half years with Kolbe in Leipzig. He has written that the return of a prodigal son from Germany was then a novelty; owing to Hofmann being in London and Liebig no longer an attraction, the habit of studying chemistry in Germany had ceased among English students: it set in again, but only gradually, owing to the enforced emigration of holders of research scholarships awarded by the Royal Commission of the 1851 Exhibition.

Armstrong worked first at the London Institution and then took the leading part in the establishment and development of the Finsbury and Central Colleges. His research school at South Kensington was worthy of the traditions of Hofmann and Frankland, and such men as Wynne, Kipping, Pope, Forster, Lowry, Heller, Rich, Renwick, Rodd and many others developed there. In the main, its students went into the chemical industry, and almost without exception they have distinguished themselves by playing a leading part in their chosen industry and its development.

T. E. Thorpe came to the College as its third professor of general chemistry and technology in 1885 from Leeds. Whereas his predecessors had been essentially organic chemists, Thorpe's interests lay in the inorganic and physical sections of the subject. He was a polished writer and also administrator and publicist. Thorpe had other wide scientific interests, taking part in eclipse expeditions and the magnetic survey of Britain. Some of his scientific work at the College concerned the determination of atomic weights—of silicon with J. W. Young, of gold with A. P. Laurie—while phosphorus compounds were studied with J. W. Rodger, Hambly and Tutton. He left to become the director of the Government Laboratories. Small in stature, he was a man of outstanding virility, and his example quickened the spirit of a band of devoted students and staff. Thorpe came back to the College on Tilden's retirement for three years to tide over the period until the Imperial College had come fully into being.

The Chemistry Department in Thorpe's days was housed in the Huxley Building in one large lecture theatre, two analytical laboratories designated North and South on the third floor, a long corridor-like room on the second floor facing west used for research, and several private rooms. The fittings and equipment, doubtless installed in 1872, were already old-fashioned. It is worth while pointing out how quickly a chemical laboratory grows out of date—a new one is required at least every thirty years. It is perhaps desirable to consider whether palatial and costly solid buildings should be erected for such purposes, or whether more simple structures would not be more practical and economical. They could be rebuilt every ten or fifteen years and kept continually up to date.

In 1894, W. A. Tilden from the Mason College, Birmingham, followed Thorpe. Much of his time was devoted to teaching and administrative duties, including that of dean (1905–8), and his own experimental work, largely concerned at that time with a systematic study of specific heat, was interrupted. His earlier researches had been in organic chemistry, notably the first discovery of the polymerization of isoprene to rubber, work in which M. O. Forster, then his private assistant, had a hand. Tilden's period covered a transference of the Chemistry Department from the Huxley Building to its present domicile in Imperial Institute Road: the design, construction and fitting of the new laboratories involved much of his time.

H. B. Baker succeeded Sir Edward Thorpe as professor of chemistry on the latter's retirement i 1912 and the opportunity was taken to found separat chairs of physical and organic chemistry to whic J. C. Philip and J. F. Thorpe respectively wer appointed in 1913. The Department was thus wel equipped to deal with chemical problems arising ou of the First World War, in the investigation of whic it took no small share. With the return of peace Baker resumed his study of the influence of complet dryness on the physical and chemical properties o solids, liquids and gases. On his retirement in 1932 he was succeeded by H. V. A. Briscoe, a former studen (1906–9) and member of the staff, who came from King's College, Newcastle-upon-Tyne, and on th retirement of J. F. Thorpe in 1940, I. M. Heilbron o the University of Manchester succeeded to the cha of organic chemistry, the chairs of chemistry revertin to two in number after the death of J. C. Philip i 1941.

In the building up of the great school of chemistr at South Kensington, the non-professorial member of the staff had a large share: some gave long an devoted service, while others in due course accepte professorships elsewhere. Only a few names can b mentioned in the space available; those omitted a in no sense forgotten by their students.

F. R. Japp was chosen by Frankland in 1878 t take charge of the Research Laboratory which wa then being established, and to devote his whole tim to the supervision of the research students. In 188 he was promoted assistant professor. Japp ha worked abroad with Kekulé and Anschütz; he spen twelve years in London, where he gathered aroun him a large number of able and enthusiastic student and research was prosecuted with great activity Finally he went to Aberdeen and founded there school of advanced chemical study.

W. P. Wynne succeeded Japp; he had been student at the College during 1881–85, and the joined H. E. Armstrong at the Central, where f many years they were jointly engaged on studies the constitution of naphthalene derivatives and the many isomeric naphthalene intermediates f dyes; the manufacture of these and of the derive dyestuffs, alas, was by then largely in German hand He returned to the College as assistant professor i 1891, but left in 1902 to go to the Pharmaceutic Society and in 1904 became professor at Sheffield.

A. E. H. Tutton came to the Normal School as student in 1883 and, after work on the oxides phosphorus in collaboration with Thorpe, began abo 1892 the measurement and description of the crysta of organic substances prepared in the Chemic Laboratory. Self-taught in the subject, crystall graphy became the dominant passion of his life, a for forty years he investigated the effect produced crystal form and physical properties by the replac ment of one element by another in a series of alli compounds. In 1895 he became H.M. Inspector Schools (Technical), Board of Education.

G. T. Morgan was a student at Finsbury und Meldola. He first went into the dye industry Huddersfield for five years, and entered as a stude at the Royal College under Tilden in 1894. There quickly passed to the staff and began a varied resear programme indicative of the width of his futu interests. He stayed there until his appointment Dublin in 1912. Four years later he went to Finsbu and in 1919 to Birmingham, becoming in 1925 t director of the Chemical Research Laborato instituted after the War of 1914–18 as part of t

Government scheme for promoting industry on scientific lines. Morgan inspired a large number of students, a high proportion of whom went into industry; and he turned his attention continually to new fields of investigation, showing remarkable versatility. Diazo reactions of aromatic diamines; organic compounds of phosphorus, arsenic and antimony; high-pressure reactions; base exchange materials; synthetic resins; low-temperature tars, were only a few phases of his activities. Few men have done more than Morgan to carry the torch kindled by Hofmann along the highways of England, and to take chemical knowledge and scientific method into the lives of many as teacher, colleague and friend.

M. O. Forster likewise started at Finsbury, then went to Würzburg, where he took his degree and came back to the Central as Salters' Company Research Fellow. He came to the Royal College as demonstrator in 1895, being promoted assistant professor in 1902, a post he held until 1913. Forster carried out a brilliant series of organic researches from the College and was an inspiring influence there. He went to British Dyes during a troubled period, was later first director of the Salters' Company's Institute of Industrial Chemistry and four years later went to Bangalore as director of the Indian Institute of Science, where he did outstanding work for Indian science.

J. C. Philip, an Aberdonian and a pupil of Japp, studied under Nernst in Göttingen, and after a year with H. E. Armstrong at the Central gave a course of lectures in physical chemistry at the Royal College at the invitation of Tilden; he became lecturer there in 1900, assistant professor when Thorpe returned to the chair in 1909, and professor of physical chemistry, a new appointment, in 1913. From then until his death in 1941, Philip was responsible for this all-important subject. He was a teacher of great ability, and did much to establish a school of research in physical chemistry in the College during a period of very rapid growth of this branch of science.

J. F. Thorpe was a student of the Royal College in 1892–93, but developed largely under the influence of Auwers in Heidelberg and of W. H. Perkin, jun., at Manchester. He came back to the College when the chair of organic chemistry was created there in 1913, and there attracted and inspired a following of staff and research students in part because of his remarkably neat and effective technique. Under his leadership, research in organic chemistry flourished in spite of the interruption caused by the First World War. J. F. Thorpe later devoted the greater part of his time to administrative work and to Government committees, but the school continued to flourish under his assistants, among whom were included Ingold, Linstead, Farmer and Kon.

The College has played its part also in the provision of standard chemical literature without which the progress of research would be greatly hampered. The famous "Thorpe's Dictionary of Applied Chemistry" was first published in 1890 in three volumes: in its compilation, Sir Edward Thorpe had the assistance of many of the College staff besides outside collaborators. A second edition in five volumes began to appear in 1912, and a third in 1921. The First World War emphasized the value of the work and the need for a further revision. This was undertaken by J. F. Thorpe and M. A. Whiteley, thus maintaining the association of the "Dictionary" with the chemistry staff at South Kensington. It has become clear that pure science and technology cannot be divorced in a dictionary, so that the fourth edition of "Thorpe" now in progress is much wider in scope. Begun by Sir Jocelyn Thorpe and Dr. Martha A. Whiteley, it is being continued by a board of editors of which Prof. I. M. Heilbron is chairman, Dr. H. J. Emeléus a member, with Dr. Whiteley as editor and Dr. A. J. E. Welch as assistant editor.

Chemists are not unmindful of the important services rendered by A. J. Greenaway (1871–81) as sub-editor of the *Journal* and *Abstracts of the Chemical Society* over a period of forty years.

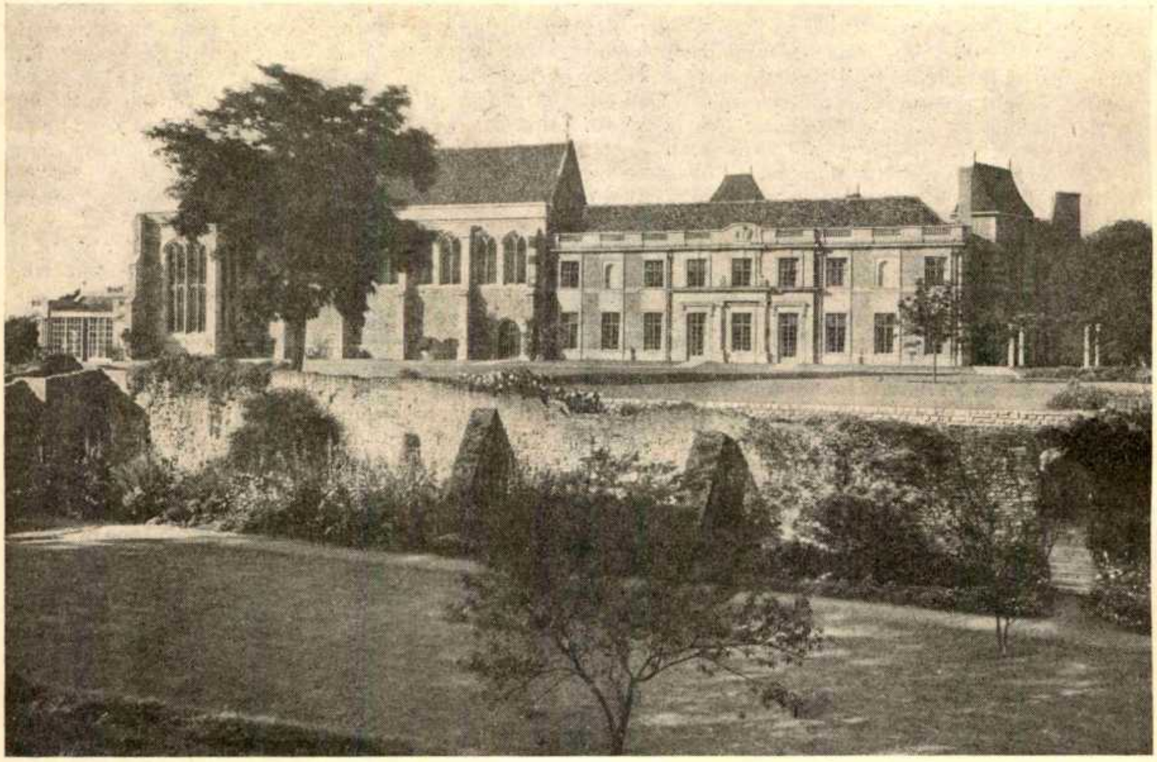
Examination of the "Register of Old Students of the Royal College of Science" confirms the impression that, in the closing years of last century, associates in chemistry found employment more easily in teaching than in industry. The title 'Normal School' was, rightly or wrongly, regarded as favouring this preference, owing to connotation with the French *Ecole normale*, although the methodology and discipline of pedagogy never formed part of the curriculum. But this preference for teaching posts need not be ascribed to predilection, as chemical industry offered relatively few openings and these none too well remunerated, with little or no assurance of security of tenure. But with the awakening of Britain to the growing need of scientific training and aptitude in industry, an improvement in prospects set in, which quickened with the growth of the present century. With the outbreak of the First World War, widespread deficiencies were revealed, and the supreme importance of research in so fundamental a subject as applied chemistry, woing to its manifold aspects in connexion with explosives, coal, oil, metallurgy, pharmaceuticals, plastics, fabrics, food products, etc., could no longer escape recognition. Then followed the establishment of the Department of Scientific and Industrial Research, with its research associations of manufacturers, and to-day cogent evidence of the imperative need of chemistry is witnessed by urgent advertisements in the daily and technical Press and combing of the Central Register for chemists. In its contribution to the yearly academic output of some four hundred first-class honours graduates in chemistry shortly before the outbreak of the present War, and their absorption in teaching and industry, it may be claimed without fear of contradiction that the College has faithfully fulfilled the purpose of its founders—that of promoting the application of chemistry to the "Arts and Manufactures".

THE ARMY SCHOOL OF EDUCATION, ELTHAM PALACE

By Major T. H. HAWKINS

ANOTHER chapter in the development of adult education in Great Britain has been begun with the opening of the new Army School of Education at Eltham Palace in Kent. To those who believe that the main cultural impact on adults is social rather than strictly educational, the choice of this historical setting with its rich associations will give real pleasure.

The Palace dates far back into history. In the time of Alfred there was "a goodly residence amidst these estates" and the dwelling and demesne are mentioned in the Doomsday Book. Edward the Confessor found spiritual calm at Eltham, and the abode was of sufficient magnificence to support the whole court of Henry III on various occasions. Edward I and II both lived for a while in this Kentish Palace, and in their time the stewardship was entrusted to Antony Bek, Bishop of Durham, who not only beautified the place, but sited and built the moat and its walls in 1300. Much of this work is extant, as is the original stone bridge built in 1396 by command of Richard II. In the reign of Edward IV the Great Hall, with its superb hammer-beam roof, was built, and since 1479 this building has stood, almost the hub of the realm in the time of Henry VII and Henry VIII, both of whom lived at Eltham, until during the Parliamentary Wars the whole estate was razed, all but the hall itself, the timbered roof and stout walls of which offered shelter to herds of cattle.



ELTHAM PALACE. THE GREAT HALL AND NEW BUILDING FROM ACROSS THE MOAT. COPYRIGHT *Country Life*.

Little restitution was effected until 1911, the Hall remaining only a rallying point for historians and painters; but in that year some repairs were made by the Ancient Monuments Department. In 1933 the lease was acquired by the Courtauld family; the Hall was restored, new wings added, and decrepit and extraneous dwellings which had encroached upon the estate were pulled down. About a year ago the lease was generously returned to H.M. the King.

Enough has been said to show that an atmosphere has been provided in which the spirit of education can unfold in the noblest of traditions. But what of the content of the educational programmes that are to be devised and carried out in the new school? This can be appreciated only by considering the background of the educational work of the Army as a whole. Before the defeat of Germany, arrangements had been made whereby every man and woman in the Army should, as soon as was practicable, be given opportunities to do six hours educational work each week. This was to be run by the Army for the Army and in the King's time. The Army Educational Corps was to be responsible for the general administration and supervision of the scheme; but in units the responsibility for organizing the educational work devolved upon commanding officers and unit education officers. The Education Branch at the War Office was charged with providing books, materials and equipment, and with drawing up necessary schedules of accommodation.

With the defeat of Germany it was decided by the Army Council that, in those units where it was possible, this Army Education Scheme should be implemented from July 1, 1945. This was carried out and, since that time, an increasing number of units, both at home and overseas, has inaugurated extensive educational schemes in their units. recent estimate, for example, suggests that abou 65 per cent of the units in one District in Great Britai is carrying out the Army Education Scheme, in fu or in part, as originally propounded. In B.A.O.R C.M.F. and M.E.F. many difficulties have bee encountered in addition to those which have bee faced by units at home; but in these theatres, to the task of providing opportunities for education activities is being tackled with good results.

This, briefly, is the picture in which the openi of Eltham Palace as an Army School of Educatio acquires significance. However near to perfecti was the gigantic Army Education Scheme as plann by the War Office Education Branch, until it w tried out in practice it could not be anything but paper scheme. Experience has already shown th in many respects the planned scheme had laid t great emphasis on what the men and women oug to demand and not, in fact, what they have d manded. The original pattern for developing the scheme which had been devised by the War Office has, in many cases, been superseded by arrangements which the units consider to be improvements on any scheme which could emanate from the War Office. In short, the infant which was perfectly conceived some months ago is now going through all the pangs of infancy.

What does the War Office do in such cases ? Many observers labour under the belief that any deviation from orthodox War Office programmes on the part of military units is tantamount to quick extinction for the individuals concerned. However much this may be true of some War Office Departments, it is certainly untrue of the Education Branch, and units have been left to develop educational schemes which would best suit their local conditions. This has led to improvisations and experiments which have enriched the scheme as a whole, and, whenever possible, new ideas and suggestions have been incorporated into the general scheme and made available for the use of other units.

Here lies one of the main purposes of the new Army School of Education. From time to time Army Educational Corps officers are to be brought in for short courses to discuss the practical difficulties which are being met with in the field and whether they are being surmounted and by what means. Most of these officers will be drawn in from home commands, but occasionally they will be joined by officers from overseas theatres, and, lest their discussions tend to concentrate too severely on the supervisory and administrative difficulties, these Army Educational Corps officers are to be joined on various courses either by the unit education officers who are concerned with the fine details of the scheme in the units themselves, or by commanding officers who are responsible for seeing that good educational facilities are being provided for men and women under their command. The interchange of ideas between those who are concerned with running the scheme on the ground and those who have planned and are responsible for the broad principles of the scheme, as well as the general details of administration, should be of great service to the soldiers and auxiliaries who are anxious to make use of the opportunities provided.

Nor can a scheme which aimed to provide educational facilities for at least six hours weekly to some four to five million adults be carried out without a large administrative and organizing staff. About a year ago the Army Educational Corps began to expand rapidly, but even apart from the expected wastages through demobilization, the number of officers in the Army Educational Corps is still very inadequate to carry out effectively their difficult role. The number of candidates who are anxious to transfer o the Corps is fortunately very high, and another of the duties of the new School is to provide courses whereby suitable applicants may be graded and assessed as to their suitability for transfer. This is done by testing their ability in organizing and instructional technique, by their contributions to discussions and the work of the School as a whole, as well as their general demeanour. Again, the interplay of ideas between those transferred and those already experienced in army education in the field hould be of considerable value to the new entrants o the Army Educational Corps.

Even then the functions of the School are not exhausted. In some theatres of war, particularly ndia, some Army Educational Corps personnel have been primarily concerned with the teaching of English to Indians and of Urdu to British personnel, and have had little chance of finding out the tremendous developments in army education during the later years of the War.

These individuals have often been overseas for periods of not less than seven years and, when they come home, feel an urgent need for 'refresher' courses where they might be brought up to date with the latest developments in army education. For these, Eltham Palace also makes provision.

So far, one course only has been held, and its success augurs well for future arrangements. The discussions between those already experienced in army education and who are anxious to share their experiences with similar individuals, those who are keen to become members of a Corps which has won good report during the War, and those whose experiences have been in other directions and who need re-orientating, have already shown the value of such a School and the interest that will accrue to it with each successive course.

One of the sessions, which should be of considerable use to adult education, is that in which officers discuss the Army Education Scheme and its carry-over to the national educational system. It is well known that, before the War, the vast majority of the adult population had been unattracted by any of the educational movements which, on the whole, had been providing sustenance only for those already converted. Bound up with this was the fact that most of the classes provided were too academic and paid too little regard to the variety of human interests. Further, there had been an unsatisfactory and unnecessary division between vocational and non-vocational subjects. From the early days of the War, Army educationists had adopted a different policy and, from the beginning, sought to provide educational opportunities not for the few but for the many. Their role as proselytes has taken them up many gum-trees ; but the spirit in which the work has been tackled has led them to attempt experiments and improvisation which have often opened new doors to the education of adults.

The new technique which has been most successful is the use of the informal discussion method for stimulating initial interest in what might, to the group, be a new subject. Another is the use of visual aids, and, already, both in direct teaching and in information rooms, the Army has set up a standard of which it is rightly proud. The value of residential education for adults has been argued persuasively by, among others, Sir Richard Livingstone, and there is no need to repeat the advocacy.

In the many hundreds of residential courses which the Army has run, considerable experience has been gained not only in the organization of such courses but also in framing programmes which would be most effective in the short periods available. Other work which has long since passed the experimental stage has been done for patients in hospitals and convalescent homes and for soldiers under sentence in military prisons and detention barracks. So, too, has the remarkable work in basic education which has succeeded in transforming the lives and values of many former illiterates. At present, experiments in the use of educational broadcasts are being made and their progress is being carefully noted.

The discussions on all these topics have been framed so that officers can make concrete suggestions from their own army and civil experience as to the most suitable means of transferring these new devices in adult education to the civil education system. Army educationists are well aware that during the War a new interest in adult education has been built up and they are anxious that this interest shall be directed into useful channels before it evaporates; hence the need for careful deliberations before the mass of men and women are demobilized and for quick action afterwards.

The Ministry of Education is fully alive to the need for the immediate capitalizing of this newly gained interest in education by adults, and it is pleasing to report that here, too, Eltham Palace is to play a useful part. At the time of writing, more than a score of His Majesty's Inspectors are attending a short course to learn the main principles of the Army Education Scheme. Very shortly they will go to commands at home and overseas to see how effectively the Army Education Scheme is working on the ground. After a few months of this field work, they will come together again, their recommendations collated and transmitted to the Ministry for any action that is thought desirable.

Eltham Palace has been on the map for some five hundred years. Its significance in history, like good wine, needs no bush. In contemporary affairs it has acquired a new meaning. That lies in the choice of the Palace as an Army School of Education with the clear recognition that worthwhile education deserves a home where it can prosper and flourish.

The Army Council is to be congratulated on securing this magnificent building for what will now become the permanent home of the Army Educational Corps. On October 25 it was officially opened by the Parliamentary Under-Secretary of State for War, Lord Nathan. He was supported by General Sir Ronald Adam, the Adjutant-General to the Forces, and many other distinguished men and women. The first Commandant of the School is Lieut.-Colonel W. S. Beddall.

OBITUARY

Prof. F. Vejdovský

Six years ago it was noted in these columns that Prof. F. Vejdovský, the distinguished Czech zoologist, was then about to celebrate his ninetieth birthday (see *Nature*, **144**, 276, 1939; with portrait). It is now learned, with regret, that he died shortly afterwards, so the following additional notes may interest his numerous friends and colleagues all over the world.

František Vejdovský was born at Kouřim (Bohemia) on October 24, 1849. After passing through the Latin School, he matriculated in the philosophical faculty (natural sciences) of the Charles University of Prague, and took his doctor's degree in 1876. In the same year he became assistant to Prof. A. Frič at the Zoological Institute. Next year (1877) he was appointed lecturer in zoology at the College of Technology (Prague). In 1879 he held the post of lecturer in zoology and comparative anatomy in the University, becoming extraordinary professor in 1884. In 1892 he was elected professor of zoology, comparative anatomy, and embryology, and thereafter continued to direct the Czech Zoological Institute until 1921, when he retired as professor emeritus. His period of office covered, therefore, the rebuilding and reorganization of the Institute, and the War of 1914–18. In addition, he was dean of the philosophical faculty in 1895–6, and Rector Magnificus of the Charles University during 1912–13. For many years he was president of the Royal Society of Sciences of Bohemia, and remained honorary president of the Zoological Society of Czechoslovakia until the day of his death. Various other societies in France, Belgium, Poland, Russia, Jugoslavia, and the United States long ago enrolled him as a member; while England, represented by the University of Cambridge, conferred an honorary doctorate upon him on the occasion of the Darwin Celebration in 1909.

For more than half a century Vejdovský was the revered *doyen* of Czech zoologists, and by his own work and his teaching exercised an enduring influence on the development of zoology in his own country. His influence was also deeply felt abroad. Most of his own researches dealt with various groups of invertebrates (Protozoa, Porifera, Turbellaria, Annelida Nematoda, Crustacea, etc.), and were morphological, cytological, embryological, and systematic. They cover an unusually extensive field. He was especially interested in spermatogenesis, and problems connected with the centrosome and chromosomes, but also devoted much study to freshwater hydrobiology. On these and other matters he published some ten large treatises and more than a hundred other memoirs in Czech, English, French, German, and Belgian periodicals. His most important works are the "Thierische Organismen der Brunnenwässer von Prag", and the discovery of the remarkable crustacean *Bathynella* (1882); the "System und Morphologie der Oligochaeten" (1884); his classical researches on *Gordius* (1886 and onwards); "Zrání, oplození a rýhování vajíčka" [Maturation, fertilization and cleavage of the ovum] 1886; "Entwicklungsgeschichtliche Untersuchungen" (1888-93); "Neue Untersuchungen über die Reifung und Befruchtung' (1907); "Zum Problem der Vererbungsträger (1912), and his final work (in English) entitled "Structure and Development of the 'Living Matter' " (1926–27)

This last book embodies Vejdovský's ultimate conclusions and opinions on many problems of cytology—on spermatogenesis, reduction, the structure of chromosomes, cytoplasmic inclusions, the origin of the centrosome, and the organization and genetic continuity of cell-constituents generally. It is a big volume of 360 pages with 24 double plates (containing 579 figures admirably drawn by his own hand), and is a notable achievement for a man nearing his eightieth birthday. Much of this work was done during the War of 1914–18, under extreme difficulties, and it completion and publication—in a foreign language—afford convincing evidence of its author's industry and erudition.

Vejdovský died at Prague on December 4, 1939 Shortly before his death, his ninetieth birthday wa celebrated by the publication of a *Festschrift* to which many of his colleagues, friends, and pupils contributed. It is an octavo of over six hundred pages with a portrait and full bibliography of his publications, and entitled "Sborník prací vydaný k 90 narozeninám Prof. Dr. Františka Vejdovského Královskou českou společností nauk a Čs. zoologicko společností v Praze [Collection of works edited fo the 90th birthday of Prof. F. Vejdovský by the Royal Czech Society of Science and the Czechoslova Zoological Society of Prague]". It forms vols. VI–VI of the Proceedings [Věstník] of the Zoological Society for the year 1938–39 (Prague, 1939). As yet onl one copy of this volume—surely unique in the annals of zoology—appears to have reached England.

CLIFFORD DOBELL.

NEWS and VIEWS

rof. W. T. Astbury, F.R.S.

IN 1928 the Worshipful Company of Clothworkers of the City of London made a grant of £3,000 a year o the University of Leeds for research purposes. Never has a grant been more fully justified, for it esulted in the appointment of Dr. W. T. Astbury as ecturer in textile physics and induced him to take up the study of proteins. A scholar of Jesus College, Cambridge, Astbury had acted as assistant to Sir William Bragg, first at University College, London, during 1921–23, and then at the Davy Faraday Laboratory of the Royal Institution during 1923–28. At Leeds, therefore, X-ray studies of hair, wool and elated fibres claimed his immediate attention, and he main features of the molecular structure of the keratins were defined in two papers published in the *Philosophical Transactions of the Royal Society* in 1931 and 1933. The industrial importance of this and other work was recognized by the award of the Gold Medal of the Worshipful Company of Dyers in 1934, and the Warner Memorial Medal of the Textile Institute in 1935. Its implications in the biological ield were even more profound: assisted by generous grants from the Rockefeller Foundation since 1933, he utilized his concept of folded and extended polypeptide chains, derived from the examination of unstretched and stretched wool fibres, to obtain a structural interpretation of the denaturation phenomenon, and, later, to identify the keratins, myosin, fibrinogen and fibrin as belonging to the same group of proteins.

The extent and importance of Astbury's work on the structure and stoichiometry of the proteins have been recognized by the award of the Actonian Prize of the Royal Institution in 1935 and the Sc.D. of the University of Cambridge in 1937; by his promotion to reader in textile physics at the University of Leeds n 1937; and by his election to the fellowship of the Royal Society in 1940. This year he has had the distinction of being the Croonian Lecturer of the Royal Society, and the many admirers of his work will now rejoice to know that the University of Leeds has elected him to the chair of biomolecular structure, which was instituted in his honour.

Royal College of Physicians: Medal Awards

THE following awards have recently been made by he Royal College of Physicians:

Moxon Medal to Sir Alexander Fleming, for his work on penicillin, as an outstanding contribution to herapeutics and clinical medicine. This award, which s not restricted to British subjects, is made to the person who is deemed to have most distinguished himself by observation and research in clinical medicine.

Weber-Parkes Prize and Medal to Prof. Eugene L. Opie, professor of pathology, Cornell University, New York, for his work on the pathogenesis of pulmonary uberculosis. This Medal is awarded every third year or the best work done whether in Great Britain or abroad upon some subject connected with the tiology, prevention or treatment of tuberculosis.

Baly Medal to Prof. S. A. S. Krogh, of the Zoophysiological Laboratory, Copenhagen, who has made outstanding contributions to our knowledge of the capillaries and of related physiological problems in cellular nutrition and respiration. This award is made every alternate year to the person who shall be deemed to have most distinguished himself in the science of physiology, especially during the two years immediately preceding the award, and is not restricted to British subjects.

Fifty Years of X-Rays

IN the history of science there have been few more unexpected and few more fruitful discoveries than that made by Wilhelm Konrad Rontgen on November 8, 1895, and described not many days after in his paper "Über eine neue Art von Strahlen" read to the Physico-Medical Society of Würzburg. Copies of the paper reached England early in 1896, and *Nature* of January 23, 1896, contained a translation of it. By those fortunately in possession of the necessary apparatus, Rontgen's experiments were repeated with delight and wonder, and not only that, they were put to very good purpose. In Berlin, on January 20, 1896, a medical man had with the new methods detected a glass-splinter in a finger, and at Liverpool on February 7, Dr. C. T. Holland found by X-rays a bullet in a boy's hand. None had received news of the discovery with greater interest than Sir Arthur Schuster, who in his book "The Progress of Physics during Thirty-three Years", published in 1911, tells how his laboratory was inundated by medical men with their patients, among whom was a ballet dancer whose trouble had been diagnosed as bone disease but who all the time had a needle in her foot. In April he and his assistants were called to Nelson, Lancashire, to a woman who had been shot by her husband and whose head Schuster explored with the new rays. There was no opposition to the application of Rontgen's discovery, as there had been to those of Lister and Pasteur, and medical science and surgery have benefited universely from it. Even after two world wars, it may be that X-rays have saved more lives than bullets have destroyed.

Medical aspects, however, are a small part of the story, for Rontgen's work influenced all physical studies. In the jubilee number of *Nature*, November 6, 1919, Sir Ernest Rutherford, as he then was, wrote that the discovery "marks the beginning of a new and fruitful epoch in physical science in which discoveries of fundamental importance have followed one another in almost unbroken sequence". Sir William Bragg said much the same thing, and none did more than these two distinguished men to further the use of X-rays for unfolding the secrets of Nature. Rontgen was born at Lennep, in the Ruhr, on March 27, 1845 (see *Nature*, March 24, 1945, p. 351), and was thus in his fifty-first year when he achieved fame. In 1894 *Nature* had referred to his collaboration with August Kundt, but he was then little known. His single observation, however, wrote his name indelibly in science, and among his rewards was the Nobel Prize of 1901. Before 1895 he had worked at Würzburg, Strassburg and Giessen and had returned to the first in 1885. His latter years were spent at Munich, first as director of the Physical Institute and from 1919 in retirement. He died there on February 10, 1923, having seen others reap a rich harvest from the seed he had sown.

Research in Britain on Atomic Energy

IT was announced by the Prime Minister on October 29 that the Government, acting in accordance with a recommendation from the Advisory Committee on Atomic Energy, has decided to set up a research and experimental establishment covering all aspects of the use of atomic energy. The station will be at Harwell airfield, near Didcot. Responsibility for research on atomic energy, which hitherto has rested on the Department of Scientific and Industrial Research, is to be transferred to the Ministry of Supply, and the Tube Alloys Directorate which dealt with such matters is accordingly being transferred to the Ministry. The whole of the cost of research in this connexion will fall on the Government. In reply to a question asking whether this change of control means that the Government is more concerned with the weapon value of atomic energy than its production value, Mr. Attlee remarked that this was not so, and that the Ministry of Supply is engaged in civilian production as well as production for the Services.

On October 30, Mr. Attlee stated in the House of Commons that he is to visit President Truman in Washington "to discuss with him and the Prime Minister of Canada the problems to which the discovery of atomic energy have given rise"; Sir John Anderson, chairman of the Advisory Committee on Atomic Energy, is to accompany him in an advisory capacity.

French Association for the Advancement of Science

THE French Association for the Advancement of Science held a large and enthusiastic Congrès de la Victoire in Paris during October 20–26. This was the first assembly of its kind to be held since 1939, the usual annual meetings having been suspended during the period of the War. At the invitation of the Association, delegates were present from Great Britain, the United States, Canada, the U.S.S.R., Argentine, Switzerland, Belgium, Sweden, Norway, Czechoslovakia and Rumania. About fifteen hundred members of the Association and the delegates were present at the opening meeting in the Great Hall of the Sorbonne on Saturday, October 20. The president of the Municipal Council of Paris opened the proceedings with a welcoming speech, which was followed by discourses delivered by Prof. Joliot-Curie and Prof. Justin-Besançon, president of the French Red Cross.

Prof. Henri Piéron, who had been elected president of the Association at the Liège meeting in 1939, delivered his presidential address after the chief delegates had paid tribute to the vitality of French science and its renewed vigour, in the addresses presented by them. The British Association delegation was headed by its president, Sir Richard Gregory, who read the address sent by the Association; the other delegates from Great Britain were Sir Thomas Holland and Dr. W. Campbell Smith, members of the Council of this Association, Sir Edward Appleton and Prof. E. N. da C. Andrade, with Lady Gregory representing the lady members. The inaugural meeting lasted from three to six o'clock in the afternoon.

The twenty-two sections met separately or jointly in six scientific institutions during the week, and with full programmes of papers. Sir Edward Appleton gave a lecture on the ionosphere on the afternoon of October 22 to a joint meeting of three sections, and he and Prof. Andrade afterwards made two short broadcasts at the request of the radio officer attached to the British Embassy. A reception was given on the evening of October 24 at the Hôtel de Ville and there was a banquet on October 25 at the Salons Vianey. At the general assembly on October 26, the president and other officers of the Association for the ensuing year were elected and other officia business transacted. On the same evening the Britis Ambassador and Lady Diana Duff Cooper gave reception at their official residence to the foreig delegates and officers of the Association and othe distinguished representatives of scientific societies i Paris.

Middle East Field Biology

THE presence of numerous amateur and professiona zoologists among the British Forces in the Middl East countries during the War has resulted in a considerable amount of field biology being carried ou in those countries, much of which is now being published. The anti-locust work of British units an frontier defence forces also aided. The Zoologica Society of Egypt has issued numerous special bulleti to accommodate these original observations, mainl upon ornithology. Bull. 7 issued in 1945 contain Shamseddin Halfawi's "Notes on Birds from Wester Saudi-Arabia". Bull. 6 contains bird notes fro Lower Egypt (autumn, 1943), and from Amriya Egypt (July–October 1942), and a list of migrant seen in Egypt, the western desert and Tripolitania while special supplements to this bulletin were devoted to papers on Palestine and Syria, and to th migration of the white stork. Bull. 2 contains valuabl notes on the birds of Suez, and Bull. 5 has notes o bird migration across the western desert and Libya Especially interesting are the bird notes from th Daedalus lighthouse in the Red Sea, augmented b the British keeper at the lighthouse, as they supplement some of the earlier work of Meinertzhagen i the First World War.

The Army itself has published much through it Middle East Biological Scheme, organized fro G.H.Q. to collect specimens for the British Museum and with naturalists' clubs in Baghdad, Jerusalem Damascus and Cairo publishing regular bulletins Collecting expeditions have been organized throug the scheme over periods of several days or weeks a Lake Tiberias, Lake Huleh, Mt. Cassius in Syria etc., the Anti-Lebanons have been surveyed, an several expeditions have been made in the Euphrate valley, bringing up to date "The Survey of Ira Fauna" published by the Bombay Natural Histor Society (1915–19), with the work on birds, mammal insects and reptiles in Mesopotamia collected an studied by soldier naturalists in Mesopotamia durin the First World War.

History and Philosophy of Science

PRIOR to 1939, the Departments of the Histor and Philosophy of Science and of the History o Medicine at University College, London, which wer the only departments of their kind in Great Britai provided either full-time or part-time postgraduat courses of one and two years. On an average th department accommodated 30–35 students. Wit the full return of University College to London th autumn, the Department has been reopened. It hoped shortly to make an appointment to the po of professor and head of the Department, which at present vacant; but, in the meantime, cours in the history of science are being provided by members of the pre-war staff. Although the session commenced on October 1, arrangements have been mad whereby intending students will be able to commen the first year's course so late as January 1946 wit out loss of opportunity.

Diseases of Cereals

CORRECT diagnosis is of prime importance for the successful prevention and control of plant disease, and considerable confusion is frequently caused by the loose use of terms such as 'blight', 'rust' or 'mildew'. The Ministry of Agriculture has accordingly published Bulletin No. 129, compiled by W. C. Moore, entitled "Cereal Diseases" (London : H.M. Stationery Office. 1*s.* net), which should prove of great value to all interested in the cultivation of these crops, whether it be the farmer, scientific adviser or student of agriculture. It provides simple, accurate and, in a number of cases, illustrated descriptions of the diseases of cereals that occur in Great Britain, together with the measures that should be taken to prevent or control their incidence. The diseases causing the most damage are yellow rust, bunt of wheat, leaf spot of oats, leaf stripe of barley, take-all, eyespot, mildew and manganese deficiency disease; but even these vary in intensity from season to season and in some years others are of equal importance. A farmer experiencing trouble with cereal crops is urged to seek advice from his County War Agricultural Committee, and a list of provincial advisory centres and advisory mycologists is appended from whom help may be obtained.

Californian Marine Algæ and Grasses

E. YALE DOWSEN has compiled a most useful "Annotated List of the Marine Algæ and Marine Grasses of San Diego, California" (*Occas. Papers, San Diego Society of Natural History*, No. 7, March 1945). This is intended primarily for the amateur, and is simplified as much as possible. Directions are given for collecting, preserving and examining marine algæ, and there are also keys to genera and list of species with habitats, notes on marine grasses, a glossary of terms and a bibliography. With this little manual much may be accomplished by anyone interested in these plant groups.

Royal Society of Edinburgh

THE following have been elected officers and members of council of the Royal Society of Edinburgh: *President:* Sir W. Wright Smith; *Vice-Presidents:* Dr. Alan W. Greenwood, Dr. E. Hindle, Dr. David Russell, Prof. R. J. D. Graham, the Right Hon. Lord Cooper, Prof. J. W. Heslop Harrison; *General Secretary:* Prof. James Kendall; *Secretaries to Ordinary Meetings:* Prof. E. T. Copson, Prof. A. Holmes; *Treasurer:* Sir E. Maclagan Wedderburn; *Curator:* Dr. John E. Mackenzie; *Councillors:* Lieut.-Colonel W. F. Harvey, Prof. A. E. Trueman, Prof. J. Walton, Prof. T. Alty, Mr. J. Morrison Caie, Sir Robert Muir, The Hon. Lord Birnam, Prof. E. P Cathcart, Prof. A. Gray, Dr. J. Russell Greig, Dr. W. A. Harwood and Prof. C. M. Yonge.

University of London

THE following appointments have been made by he University of London: Dr. A. I. Richards, pecial lecturer in social anthropology at the London School of Economics, has been appointed to the University readership in anthropology tenable at the School as from October 1. Dr. Margaret Read, lecturer in social anthropology at London School of Economics and since 1940 head of the Colonial Department at the Institute of Education, has been appointed to the University readership in education tenable at the Institute of Education as rom October 1.

Dr. James Henderson, lecturer in mathematics at King's College, London, has been appointed academic registrar of the University as from January 1, 1946, in succession to Colonel S. J. Worsley, who has been appointed principal of the College of Estate Management.

The following doctorates have been conferred: D.Sc. on Robert Brown (Imperial College); D.Sc. (Eng.) on C. M. White (Imperial College); D.Sc. (Eng.) on Norman Davey.

Announcements

THE Nobel Prize for Medicine for 1945 has been awarded jointly to Sir Alexander Fleming, of the University of London, Sir Howard Florey and Dr. E. B. Chain, of the University of Oxford, for their work on the discovery and utilization of penicillin.

SIR JOHN BOYD ORR has been appointed the first director-general of the United Nations Food and Agricultural Organization.

DR. H. LIPSON, of the Cavendish Laboratory, Cambridge, has been appointed head of the Department of Physics in the Manchester College of Technology in succession to Dr. W. H. Taylor.

PROF. L. P. GARROD, professor of bacteriology in the University of London, is visiting Belgium to lecture on penicillin to medical audiences, at the invitation of the University of Louvain and under the auspices of the British Council.

THE British Association announces the reopening of the Charles Darwin memorial rooms at Down House, Downe, Kent, daily excepting Fridays, from 11 a.m. to 5 p.m. The exhibits were uninjured during the War, and since they were last on view a number of additions have been made.

THE Council of the Geological Society of London has accepted an offer made jointly by the Anglo-Iranian and the Burmah Oil Companies to provide a fund of £750 per annum, for an initial period of seven years, to be used to defray the costs of an instructional tour for about twenty students taking honours courses in geology at various universities and colleges. Each tour will probably extend over three weeks and will include visits to classic geological sections. It will be arranged to supplement the field instruction normally provided by the universities.

DR. E. W. GUDGER, Department of Fishes, American Museum of Natural History, New York City 24, N.Y., states that the "Bashford Dean Memorial Volume: Archaic Fishes" is now complete in Articles I–VIII, plus index, introduction, two title pages and two tables of contents—for binding as Parts I and II. Those who receive such material regularly from the American Museum are invited to apply for any parts which may be missing. Duplicate lithographed plates of the segmentation of the egg (2) and of the genital system of *Bdellostoma* (4) are also available.

REFERENCE was made in *Nature* of October 27 (p. 502) to the commemoration of the anniversary of the discovery of X-rays. The joint meeting of all the participating societies will be held at the Phoenix Theatre, Charing Cross Road, London, W.C.2, on November 9, at 3.30 p.m., instead of at the Central Hall, Westminster, as originally arranged. There will also be a small exhibition of historical apparatus in the Reid Knox Hall of the British Institute of Radiology, 32 Welbeck Street, London, W.1, during November 8–10 (10 a.m.–6 p.m.).

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

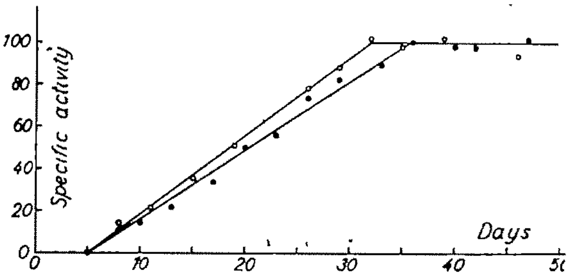
Life-Cycle of the Red Corpuscles of the Hen

THE life-cycle of the mammalian red corpuscles is not known with certainty. Values varying between 30 and 200 days are recorded. One would expect the problem to be easily solved by making use of an isotopic indicator, that is, by labelling the corpuscles. In trying to find a suitable indicator, great difficulties are encountered, due to the fact that almost every compound present in the corpuscles is renewed at a comparatively rapid rate. Only such labelled molecules which have a longer life-time than the red corpuscles in which they are located can be used as indicators. Iron atoms incorporated with hæmoglobin molecules remain unchanged during the life-time of the red corpuscles[1]. Hahn and his colleagues[2], however, found that the iron atoms contained in the debris of the hæmoglobin of decayed corpuscles are preferentially used in the formation of new corpuscles. This fact makes radioactive iron unsuitable for the determination of the life-cycle of the red corpuscles.

We found desoxyribose nucleic acid phosphorus to be a suitable indicator for the determination of the life-cycle of nucleated corpuscles. In contradistinction to desoxyribose nucleic acid molecules present in various organs, those found in the red corpuscles of the hen are not renewed at an appreciable rate. In experiments *in vitro*, in which hen blood was shaken in an oxygen atmosphere in the presence of labelled sodium phosphate, no active desoxyribose nucleic acid was found to be formed, in contradistinction to other active phosphorus compounds. Furthermore, activity was absent in the desoxyribose nucleic acid present in the circulating red corpuscles of the hen up to five days after administration of radioactive phosphate.

Hen corpuscles, labelled by their active desoxyribose nucleic acid content, can be used in two different ways. We can administer, for example, labelled phosphate to the hen, and after the lapse of a week replace part of the corpuscles of a second hen by labelled corpuscles of the first one. When taking blood samples at intervals, we can determine what percentage of the transfused corpuscles is still present in the circulation of the hen. In a note to be published later, we shall communicate the results obtained in such experiments. In this note we shall describe another method in which, by avoidance of blood transfusion, the uncertainty about the equality of the life-time of the transfused corpuscles and the endogenous corpuscles can be eliminated.

In the latter method, labelled phosphate is administered twice a day to the hen in such quantities that the plasma phosphate is kept at a constant or almost constant level of activity. The active phosphate penetrates into the marrow and participates in the formation of the nucleic acid of the corpuscles, which thus become labelled. The percentage of labelled corpuscles will increase with time, and finally the circulation will contain labelled corpuscles only; thus the activity of 1 mgm. corpuscle desoxyribose nucleic acid phosphorus will be equal to the activity of 1 mgm. marrow phosphorus and 1 mgm. plasma phosphorus respectively.



LIFE-CYCLE OF THE RED CORPUSCLES OF TWO HENS. ABSCISSÆ: DAYS AFTER START OF EXPERIMENT; ORDINATES: SPECIFIC ACTIVITY OF DESOXYRIBOSE NUCLEIC ACID PHOSPHORUS EXTRACTED FROM THE CORPUSCLES SECURED AT DIFFERENT DATES.

The results of such experiments are shown in th accompanying graph, which makes it clear that i the first five days the nucleic acid present in th corpuscles is inactive. This may be interpreted b assuming that, in the first phase of the experiment corpuscles containing inactive nucleic acid reach th circulation, and that it is about five days befor corpuscles containing labelled nucleic acid are give off by the sinusoids to the circulation. The maturin of the corpuscles in the marrow thus takes abou five days. The graph also shows that, after the lapse o about thirty-three days, the maximum value of th activity of the desoxyribose nucleic acid is reache Taking into account that in the first five days n labelled corpuscles intrude into the circulation, th life-time of the red corpuscles will be 28 days. It of interest finally to note that the results obtaine indicate that all or almost all corpuscles present i the circulation have a similar life-time.

We wish to express our cordial thanks to Pro Niels Bohr, director of this Institute, and to Pro August Krogh and Dr. Albert Fischer in whos laboratories the investigation was continued whi the Institute of Theoretical Physics was under enem occupation.

Departure of Long-Wave Solar Radiatio from Black-Body Intensity

IN some recent experiments of great interest an importance, both Reber[1] and Southworth[2] hav succeeded in detecting and measuring solar radiatio in the short-wave end of the radio spectrum. T wave-length employed by Reber was 187 cm., whi the three wave-lengths used by Southworth, althoug not precisely specified, were of the order of 10 c and less. In both series of experiments it was foun that the intensity of solar radiation approximate conformed to that emitted by a black body at temperature of 6,000° K. In another series of expe ments of somewhat allied character, Jansky is r ported to have been unable to detect solar radiatio using a longer wave-length of 14·6 metres, althoug his apparatus was sufficiently sensitive to detect t electromagnetic radiation, which he discovered i 1931, coming from the vicinity of the Milky Way.

The object of this communication is to point out that there is evidence from radio reception experience, dating from the period of the last sunspot maximum, which suggests that during periods of marked solar activity, the sun occasionally emits radiation in the radio spectrum greatly in excess of black-body radiation corresponding to 6,000° K. Reber and Southworth do not appear to have observed these effects, possibly because their work was conducted during the present period of sunspot minimum.

My attention was first attracted to this phenomenon of abnormal solar radiation by Mr. D. W. Heightman (Amateur Station *G6DH*), who described hearing in 1936 a hissing sound when receiving in the range of 10–40 Mc./s. Other amateur observers sent me further excellent reports, from which I concluded that the noise was due to the emission of *electromagnetic* radiation from active areas on the sun. The noise was heard only in day-time and was often the precursor of a catastrophic fade-out associated with a bright eruption on the sun. It will be recalled that such fade-outs are due to marked intensification of *D*-layer ionization caused by outbursts of ultraviolet light from active solar areas; and it is natural to associate the radio noise heard before the fade-outs with the same areas. On the frequency band of 10–30 Mc./s. this temporary *D*-layer ionization is usually sufficient to attenuate the solar radiation which causes the noise; though from our knowledge of the magnitude of such attenuation, which varies as λ^{-2}, I should expect that extremely short-waves would make the single journey through the layer with only slightly diminished strength and so be detectable both before, and throughout, the fade-out.

It is possible to get some quantitative idea of the enhancement of the short-wave radiation from the sun on such occasions, for it is easy to show that the black-body radiation (although recently detected on extremely short waves) would be quite undetectable on the type of receiving aerial used in ordinary short-wave reception. The flux of solar energy received at the earth's surface is given by F, where

$$F = \frac{2\pi kT}{\lambda^2}\left(\frac{r}{R}\right)^2 \Delta f \text{ (ergs, cm.}^{-2}\text{, sec.}^{-1}) \quad . \; . \quad (1),$$

where k is Boltzmann's constant, T the effective solar temperature, λ the wave-length, r the radius of the sun, R the earth-sun distance, and Δf the frequency-acceptance band. Now if we receive such radiation using tuned half-wave dipoles as aerials, the power absorbed is proportional to λ^2 (Δf being kept constant). Therefore, with aerials of this type, the solar noise should be *independent* of wave-length. In fact, the received power is given by p, where

$$p = 0{\cdot}41kT\left(\frac{r}{R}\right)^2 \Delta f \quad . \quad . \quad . \quad (2)$$

Now it is easy to show that this power is only about 10^{-4} of the receiver noise associated with earth-surface temperature and, for that reason, solar radiation does not obtrude in wireless receivers of ordinary type.

When extremely short waves are used, however, it is possible to employ directive aerial systems (for example, parabolic mirrors) of large power gain G_r, and when such a system is appropriately oriented towards the sun, the value of p is increased by the factor G_r. It is therefore clear that to detect solar black-body radiation at *any* radio wave-length, it is necessary for the aerial power gain (relative to a half-wave dipole) to be of the order of 10^4. But with the wave-lengths used in long-distance reception, an aerial array giving a power gain of this order would be of prohibitive size; and in the cases of amateur reception cited above, the value of G_r cannot have been much greater than 4. It is therefore clear that during the periods when the noise was observable, the intensity of the solar radio flux from the active area was about 10^4 times that associated with the black-body radiation from the disk as a whole.

During the next period of sunspot maximum (1948–49), it should be possible to examine more fully the frequency spectrum of these additional radiations both before, and during, fade-out conditions, since sensitive receivers in the micro-wave region are now available. Indeed, with centimetre-wave sets using very large mirrors, and thus narrow cones of energy acceptance, it should be possible to examine one particular section of the sun's disk at a time and so roughly to locate the active areas. It should, however, be mentioned that, so far as the ordinary black-body radiation is concerned, once the cone of energy acceptance of the aerial system just accommodates the solid angle subtended by the sun's disk, there is no point in increasing the mirror size further; for any additional power gain effected by such an increase is then just compensated by the reduction in the area of the solar disk which can be 'seen' by the 'radio-telescope'.

Indexes of Data for Identification Purposes

FOR the purpose of identifying crystalline solids three indexes have been initiated. (1) The Barker index of morphological data (derived from measurements of interfacial angles on single crystals) was outlined in his book "Systematic Crystallography" (1930) and reviewed by Spiller and Porter[1] in 1939. It will include all crystals (other than cubic, to which the method is not applicable) in Groth's "Chemische Krystallographie", which was completed in 1918. These number some 7,300. To these may be added the (probably small) number of compounds studied goniometrically since 1918. (2) Data on the refractive indexes of upwards of a thousand substances have been collected by Winchell in "The Optical Properties of Organic Compounds"[2]. (3) The index of X-ray diffraction data[3,4] sponsored by the American Society for Testing Materials and the Institute of Physics covers some 2,500 substances, including those in the supplement now in preparation.

Since the professed object of these indexes is that they will facilitate the identification of unknown substances, they must first be judged from this purely utilitarian point of view. Two questions immediately present themselves, namely, how often is anyone faced with the problem of identifying a solid substance, and how useful are these indexes for the purpose, and/or how useful are they likely to become within a reasonable time? We may assume that problems of identification are likely to be confined almost entirely to industrial or analytical laboratories. Also, something of the chemical nature of the substance will generally be known. Now the number of organic compounds known is of the order of 250,000 and of inorganic compounds probably some 40,000. With the above numbers in view, it is clear that at present the chances of identifying an *unusual* substance with the help of any available index are negligible. In the case of organic compounds, a really comprehensive index is obviously out of the question. Anyone tackling a specific identification problem in a specialized field would be more likely to succeed by taking X-ray photographs of a number of related compounds, particularly as the compound may not have been prepared before. It is also clear that unless the task of expanding these indexes is taken very seriously, more comprehensive compilations including other physical properties would be of greater practical value, assuming always that this problem of identifying unknown substances is sufficiently important to justify the labour involved.

Now although the X-ray index is likely to grow much more rapidly than the other two, it suffers from a grave disadvantage. Certain large groups of compounds, for example, complex oxides and sulphides and alloy systems, are notable for their variable compositions and hence variable lattice constants and intensities of reflexions. This is a serious matter in a classification based on the spacings and intensities of lines on powder photographs. It must be remembered that the X-ray index, being purely a 'fingerprint' system which does not add to our knowledge of any physical constants, must be judged solely on its merits as a means of identification. Before much more time and money are spent on such projects it would seem advisable to consider (*a*) the actual or potential practical value of any index, bearing in mind the points raised above, and (*b*) the most desirable form of index, that is, the nature and arrangement of the data therein.

Hydrogen Overvoltage as a Factor in the Corrosion of Metallic Couples

CONSIDERABLE confusion has been caused in the past by neglect of the influence of the hydrogen overvoltage on the corrosion current between metallic couples in electrolytes.

It would seem that there should be no current flow unless the potential difference on open circuit is greater than the hydrogen overvoltage at the cathode; but that when the potential difference is higher than the overvoltage, the current should depend on the difference between the two.

Work at present in progress confirms this view, and we may quote the case of magnesium alloy and copper in sea water. Copper is far removed from magnesium in the electromotive series and has a fairly low overvoltage. A couple of copper and magnesium alloy should thus give a large corrosion current; this, in fact, has been found to be the case.

By amalgamating the copper with mercury, which has a high overvoltage, and in addition is far from magnesium in the electromotive series, the corrosion current is reduced to a very small value. This value, in fact, is much smaller than that obtained with a magnesium/zinc couple, in spite of the fact that zinc is comparatively close to magnesium in the E.M.F. series.

It may be added that the known effect of surface roughness of the cathode on the overvoltage is found to have the expected effect on the corrosion current

Where ready access of oxygen is possible, the hydrogen overvoltage is accordingly reduced, and the corrosion current is able to reach a higher value in such localities.

Difference Tones

THE interesting question raised by Prof. F. Allen's letter in *Nature* of July 21 is whether the difference tones he observes are present in the air or whether they exist only in the auditory system of the listener If the loudspeaker to which the two oscillators are connected (whether in series or parallel is only a matter of impedance matching) is strictly linear in its amplitude response, then no combination tones sum or difference, will be produced. The ear, on the other hand, is far from linear in its amplitude response so when two high-pitched tones are heard together the difference tone is often clearly audible while the sum tone may be less easily distinguished or above the limit of audibility, depending on the pitch of the beating tones. However, if the loudspeaker is non linear, combination tones will be physically present in the air nearby and could be detected by a linear tuned sound analyser. If this is not available it should be possible to feel or even see the low frequency vibration of the loudspeaker diaphragm when the two tones are nearly in synchronism.

Transplantation of the Heart

FOR a number of years, my laboratory has bee studying the problem of transplanting the heart o vertebrate animals. In the animal kingdom man necessary prerequisites exist for carrying out th important, and at first sight impossible, operatio The first stage, 1938–42, was my work on cold blooded animals—frogs and fishes. After a number o experimental variants and the perfection of the operation technique, I succeeded in transplanting to frog a second heart taken from another animal; planted the second heart in the same pericardium as the heart of the host. Animals with two hearts showed no differences from control frogs, and experienced biologists invited to examine them were unable to distinguish one from the other. Two hearted frogs went through the usual nuptial period in spring, and cast their spawn in the ordinary way

As this series of experiments proved successful, then began the next series, the purpose of whic was to replace the heart of a host animal with that of another animal—a much more complicated task. The operative technique required by this series of operations was also more complicated; but after persistent attempts all difficulties were overcome.

In 1943, I removed the heart from a frog and transplanted another heart into the same pericardium. Two or three minutes after the operation, it was impossible to distinguish the operated frog from control specimens. Some of these frogs lived more than a hundred and ninety days, which is more than six months, and their behaviour did not in any way deviate from normal. In the spring of 1944, they went through a nuptial period which also ended in casting spawn.

Six months later, microscopic examination of blood vessels that had been sewn together showed that hey had knitted completely, and that the structure of the heart muscles was normal.

When there are two hearts beating in the breast of one frog, they have entirely different relations to he animal organism. The host's own heart has both neural and humoral connexions with its organism hrough blood, while for the first thirty-five–forty days the transplanted heart has only humoral chemical connexions; the nerves of the host then begin to grow on to the transplanted heart.

It is also possible to study the action of a number of cardiac medicaments on organisms with two hearts. There is undoubted interest in the question of the length of time taken by the transplanted heart o take root in the host's organism, when the host's nerves grow on to it, and what happens to nerve ganglions inside the heart.

The success of these experiments on cold-blooded animals led me to repeat the experiments on rabbits, ats and dogs. As a preliminary measure, we carefully developed methods of joining the blood vessels of warm-blooded animals; the method we developed s exceedingly simple and rapid—it takes twenty to thirty seconds to perform.

In the first series of these experiments, we developed methods of transplanting the heart into the necks of these animals. In this series of experiments, the second heart had only its right half joined nto the host's blood circulatory system. The left half of the heart was not 'in circuit'. This system we called the 'semiclinical' method.

Observations showed that the heart worked well nd would live for a long time. The heart retained s own rhythm and had no adverse effect on the lood pressure of the host or its ability to perform work.

For the second series of experiments, after a long earch for the correct method, we transplanted hearts nto the necks of hosts with both halves, arterial nd venous, in circuit with the blood circulatory ystem. This gave us a complete second heart, 'clinical ansplantation', as we called it.

Animals on which we experimented—rabbits, cats nd dogs—easily withstood the operation with very mall loss of blood and without any visible effect n the work of their own hearts.

Operated animals did not show any shortness of reath, spasms or excessive excitation after operation. They reacted normally to all external exciting gents, such as light, sound and pain.

Transplanted hearts retained their own individual hythm, which as a rule is slower than that of the ost's heart.

A method has been developed for the simultaneous registration on a kymograph of the work of both hearts. This is a valuable method of studying various theoretical problems of heart treatment, humoral and neurohumoral, in warm-blooded animals with two hearts.

After having mastered the transplantation of a second 'clinical' heart in warm-blooded animals, my laboratory is now carrying out long-term experiments for the purposes of keeping animals with two hearts alive as long as possible. Simultaneously, we are conducting experiments on the transplantation of hearts into the abdomen.

Behaviour of the Common Centipede *Lithobius forficatus*

ALTHOUGH the Chilopoda are a widely distributed order, they have attracted little notice from zoologists. Centipedes are carnivorous, feeding on insects and their larvæ, and occasionally worms and other small animals. The account by F. G. Sinclair in "The Cambridge Natural History" (1895) is still the most comprehensive survey of the group; but recent observations are at variance on certain points. Sinclair describes the breeding habits of *Lithobius forficatus*, and states: "If the male Lithobius sees the egg, he makes a rush at the female, seizes the egg and at once devours it". No reference is made as to the manner in which centipedes recognize their food, but it is implied that the sense of sight is used. Now *Lithobius* is almost invariably nocturnal, and can only be found in day-time underneath stones and piles of dead leaves. That it is negatively phototactic and positively thigmotactic has been confirmed by simple experiments. The eyes are clusters of ocelli, 25–50 in number, present in many groups of Lithobiidæ but absent in some. It would appear unlikely that the sense of sight is used in the recognition of food, and indeed, this has been proved experimentally by painting the eyes with black pigment. Nor is the sense of smell employed. Experimental observations indicate that *Lithobius* hunts for its prey by the sense of touch, which is extremely sensitive. Centipedes appear oblivious to the presence of food unless they happen to touch it with the base of the antenna.

In this connexion, the following extract from the section on "The Scolopendra and the Galley Worm" in Buffon's "Natural History" published January 31, 1782, is of interest: "Of theſe hideous and angry inſects we know little except the figure and the noxious qualities . . . they are covered with hair, and ſeem to have no eyes; but there are two feelers on the head, which they make uſe of to find out the way they are to paſs. . . ." The antennæ are covered with sensory hairs, and are continually cleaned with the maxillæ. The legs are periodically cleaned in the same manner, but less frequently. Removal of the antennæ renders the animals powerless to avoid obstacles; but they may blunder into and eat dead flies, etc., placed in their cage.

Centipedes can live for many weeks without food provided that they are kept in a damp environment. Cannibalism becomes apparent if one of the animals is particularly small or has been injured. After killing its prey, *Lithobius* seeks a soft spot by prodding with the poison claws; grips firmly with the 2nd maxillæ (sometimes assisted by the poison claws) and gnaws with the mandibles, the muscles of which can be observed through the integument of the head. I have often observed one *Lithobius* snatch at a dead fly being eaten by another centipede. If the attempted robbery proves unsuccessful, the robber may give the other a sharp, but not fatal, nip with the poison claws (maxillipeds) to make it drop its prey. Occasionally two centipedes are to be seen feeding on the same insect.

Lithobius can survive several hours immersion in water. At first it struggles violently, sometimes swimming (like *Nereis*) by a series of rapid flexions; but its motions soon become sluggish. Centipedes become darker when placed in dry surroundings than in a damp environment. This colour change is not affected by light, adrenaline, etc.; it also occurs in dead centipedes and is probably a physical change in the integument.

In conclusion, it can be stated that, except the eyes, which do not appear to be of much importance, the sense organs of *Lithobius forficatus* are in the form of hairs, or groups of hairs, each fitting into a cup in the cuticle, and connected with nerve fibres. In consequence, the behaviour of the animal is (with the exception of negative phototaxis which occurs even when the eyes are covered) chiefly governed by reactions to thigmotactic stimuli.

Hatching of the Egg of *Ixodes ricinus* L.

The mechanism of hatching in the sheep tick does not seem to have been previously described. When freely laid, the eggs are oval, but deposition in crevices results in a certain amount of flattening. Examination of the egg under the microscope reveals that the brown colour is due to a thin semi-transparent shell, covering the brown internal mass. Each egg is surrounded by a gelatinous secretion produced by Gené's organ. Immediately after oviposition, the individual egg weighs 0·00006 gm.

The pre-oviposition period varies with the season and with the individual, but usually lasts 15–22 days[1]. Prior to hatching, the larva shows very little activity, and the density of the internal contents precludes any detailed observations upon it. Twenty-one to thirty days after oviposition, at 60° F., and a relative humidity of 80, the eggs show an extensive white area of an abbreviated dumb-bell shape, surrounded by the yolk. During the forty-eight hours before emergence, the body of the arachnid comes to fill the egg more completely; the yolky contents of the gut become apparent, with small interspersed fat globules. Occasionally rhythmic movements of the head are obvious. It is suggested that at this period the larva swallows the amniotic fluid in much the same way as insects do[2]. When this fluid is added to the fatty contents of the gut, the fat globules run together to form large droplets.

At this stage the larva is enclosed in a membrane, the first or 'embryonic' cuticle, which surrounds each limb in an unsegmented sac; but in view of its smallness the limbs are very much crumpled. The head is flexed ventrally and is not visible from the dorsal aspect. Viewed ventrally, the appendages a closely apposed to one another and to the bod generally.

Within twenty-four hours of hatching, the outwar form of the egg is changed, becoming longer an thinner. Air enters the egg shell and occasionall some air may be swallowed by the larva. This, how ever, is not constant and seems to play no essenti part in the process of hatching. The enclosed larv extends the posterior part of the body and ruptur the egg shell longitudinally. It is believed that th rupture of the egg shell follows a distinct line weakness, as similar cleavages have been obtaine by the treatment of newly deposited eggs wit dilute and concentrated acids.

No air appears to be swallowed after hatchin The posterior end of the body invariably emerg first and the anterior portion of the body may b retained for some hours within the egg shell. Ulti ately, by slow movements of the legs, the entire bod comes out of the shell and the larva crawls som distance from the remains. At this stage the hea is still reflexed, of a very pale almost transpare character, and the legs but lightly sclerotized. Th tick remains quiescent with its legs drawn close to the side and head reflexed for 7–10 days at 60° and relative humidity of 80 per cent.

A fuller report on this investigation will be presente elsewhere.

Control of Foot Rot (*Phoma* sp.) of Fla

With regard to the reference[1] made to the use 'New Improved Ceresan' for the prevention of fo rot (*Phoma* sp.) of flax, further experimental wo has given the following results. Seed with a moistu content below 10 per cent and treated with this di infectant at the rate of 12 oz. per cwt. showed adverse effect of the treatment on germination wh kept for 18 weeks in hundredweight lots und ordinary storage conditions. Tests made with see on porous dishes placed on damp sand showed th the germination of treated seeds was 75 per cent compared with 95 per cent in the case of the u treated. This adverse effect was also apparent wh seeds were sown in soil in the greenhouse. No effe on germination was observed when the seed had be stored for 8 weeks. Seed from the same lot as t above but treated with 'Arasan' at the rate of 12 per cwt. and stored for 18 weeks under similar co ditions showed no reduction in germination.

When seed having a moisture content of 14 cent was treated with 'New Improved Ceresan' the rate of 12 oz. per cwt. and tests made within days, it was found that the germination was reduc from 65 per cent in the untreated seed to 46 per ce in the treated. It should also be stated that in t case of the treated sample an additional 23 per ce of the seeds showed abnormal growth on germinati The damage caused by treating damp seed has a been demonstrated by sowing seed in soil.

It would therefore appear to be inadvisable treat flax seed with 'New Improved Ceresan' if t ed has a moisture content greater than 10 per cent. n the case of seed with a moisture content less than 0 per cent, and where 'New Improved Ceresan' is sed, a period of not more than eight weeks under ood storage conditions should be allowed to elapse etween treating and sowing.

Nature, Nurture and Probability

SINCE Galton, it is customary to consider that aracters are due to nature or to nurture, or to oth, and that there is no third cause. From a ractical point of view, however, factors of chance n surely be supposed to play a part. To clarify is conception, let me take an example.

A malignant tumour is caused by some single cell r group of cells reverting to the fœtal stage and viding afresh. If this is due to hereditary factors, e should expect a general tendency in the cells of a iven tissue towards malignity. In that case, cancer ould appear concurrently at several places. This is ot so, however, which is why it is possible to treat ncer operatively. The same holds for the external vironment. If this environment caused a tumour arise, we should also as a rule expect an extensive rmation of tumours. It is difficult to imagine vironmental factors with an action on a single oint.

But there is a third possibility. Let us assume a ereditary disposition to cancer, entailing a tendency wards faulty behaviour of a certain type among e cells, for example, in cell division. Let us further sume that the hereditary tendency towards such ulty behaviour is extremely weak, and that on is account there is, for example, a 1 : 30 probability at an individual may be overtaken by such de- ction each year when he gets older. This means at, among the extremely large number of cells esent, and the very large number of cell divisions process, the probability for each cell to become a ncer cell is diminutive. If we reckon per individual stead of per cell, the tendency becomes much eater. If it is 1 : 30 a year, this implies that one of pair of monozygotic twins might get cancer relatively rly, while the other would not get it until 30–40 ars later. In most cases, then, the second twin in irs of this kind should die from a disease other an cancer. The difference between monozygotic d dizygotic twins in respect of the occurrence of ncer should therefore be very small. This being , studies on twins cannot be used to determine e part played by nature and nurture.

The situation can be illustrated by an analogy, ich must not, however, be taken too far. Let us sume that, in two large towns, the population has actly the same heredity and lives in the same vironment. Let us assume further that this results a great infrequency of suicide, so that the prob- ility for such an act in any one year is 1 : 30. a suicide then occurs in one of the two towns ring any given year, it may be many years before suicide occurs in the other town.

The conception of probability is therefore used at several different points in genetics, primarily in the distribution of the genes over the sex cells, and in their combination, secondly in genotypical asymmetries[1], and finally in certain other characters, where internal processes of a complicated nature are in process. The formation of cancer is an example of this. Similar conditions can also be thought to play a part in mental characters. From this point of view, the result of twin research in mental diseases may appear to some extent doubtful, since when processes of the kind touched on here are involved, the differences between monozygotic twins will be relatively large, and can by no means be taken as a gauge of the influence exerted by external environment.

A Forecast of Solar Activity

I WISH to direct attention to the fact that a relatively long period of intensive solar activity seems to be imminent. If this should be the case, the coming years will probably be very suitable for studying possible relations between sunspots and such terrestrial phenomena as are supposed to be allied to solar activity.

While exact predictions of the future course of sunspot numbers are impossible, forecasts with a high degree of probability can be derived from the probability laws of sunspot variations which I have published[1]. These forecasts may be summarized as regards the present new spot cycle as follows:

(1) It can be expected with a probability of 0·95 that the next sunspot maximum will be higher than the previous one, which occurred in 1937. It may be noticed that the height of the maximum of 1937 itself exceeded the heights of the five preceding maxima, which occurred in 1883, 1894, 1906–7, 1917 and 1928. Hence it seems very probable that the next maximum will be the greatest within living memory.

(2) It can be expected with a probability of 0·95 that the next sunspot maximum will occur before May 1948. At the meeting of Section D (Astronomy) of the American Association for the Advancement of Science held on September 14, 1944, S. B. Nicholson, of Mt. Wilson Observatory, reported that solar activity reached its last minimum as late as in April 1944; thus it follows from (1) and (2) that in the new spot cycle the ascent from minimum to maximum will probably be unusually steep.

(3) It can be expected with a probability of 0·98 that after the next maximum, solar activity will decrease so slowly that not until more than five years after this maximum will Wolf's smoothed sunspot numbers fall below a quarter of their maximum value. Such a slow decline has occurred in only four out of the seventeen spot cycles which have been observed hitherto.

YEAST HEXOKINASE AND ITS SUBSTRATES *d*-FRUCTOFURANOSE AND *d*-GLUCOSE

By Dr. A. GOTTSCHALK
Walter and Eliza Hall Institute of Research in Pathology and Medicine, Melbourne

On solution in water, *beta d*-fructopyranose, the only crystalline form of *d*-fructose, exhibits mutarotation which mainly consists in a pyranose $\rightleftharpoons$ furanose interconversion[1,2]. In experiments at 0° C. and $pH = 4 \cdot 5$, under which conditions mutarotation proceeds the slowest, it was previously[3] shown that *beta d*-fructopyranose added to a suspension of baker's yeast in 0·1 *M* KH_2PO_4 is unfermentable, whereas *alpha d*-glucose is fermented at the expected rate. Since in any quantitative consideration of the composition of a *d*-fructose solution at equilibrium ($pH = 4 \cdot 5$) open-chain forms (keto-form, enol-form) can be neglected, *d*-fructofuranose, chiefly present in the *beta* configuration, remains as the only fermentable isomer. The non-fermentability of *d*-fructopyranose—obviously due to lack of an OH-group at C_5—rendered possible the determination of the proportion of the furanose form in an equilibrium mixture of *d*-fructose at 0° C.; this proportion was found[4] to be 12 per cent. From this figure and the known differences in mutarotation of *d*-fructopyranose at 0° C. and at 25° C., it can be calculated that an equilibrated *d*-fructose solution at 25° C. contains approximately 22 per cent of the sugar in the furanose modification; it is in this way that the concentrations of fructofuranose given in this report have been derived.

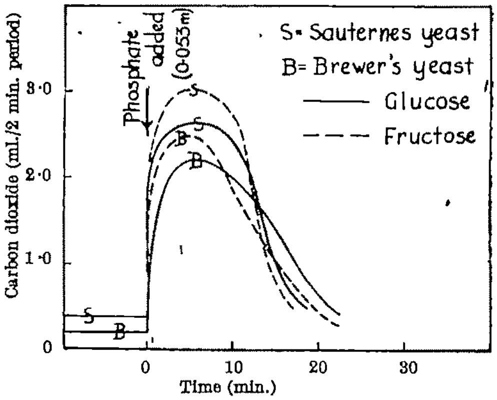
Recent experiments with sucrose as fermentation substrate have justified the aforementioned conclusion, thus confirming a hypothesis first advanced by Hopkins[5]: 0·002 *M* sucrose in phosphate solution ($pH = 4 \cdot 5$) was fermented by baker's yeast at 0° C. with conditions so arranged that 50 per cent of the disaccharide added was already inverted within 70–80 sec. It was found that after fermentation periods of 20 or 40 minutes, approximately equal amounts of *d*-glucose and *d*-fructose are left, in contrast to the preponderance of *d*-fructose in the residual aldehyde-ketose mixture when sucrose is fermented at 25° C.

With *Sacch. cerevisiæ* (brewer's top and bottom yeast, distiller's yeast) the ratio of the maximum velocities of the separate fermentations of *d*-fructofuranose and of *d*-glucose at 25° C. is 1·05[6]. It is, however, well known that Sauternes yeast ferments fructose much faster than glucose at any concentration[5,7]. It can be seen from the table that at 25° C. Sauternes yeast ferments 0·019 *M* fructofuranose at a rate 72 per cent greater than that at which it ferments 0·055 *M* glucose; at these concentrations both sugars are fermented by brewery bottom yeast at the same rate. These figures were recently obtained with a pure culture of Sauternes yeast which Pr R. H. Hopkins, University of Birmingham, kind procured for me from the Institut Pasteur, Paris.

Relative rates of fermentation by living Sauternes and brewer's yeast in 0·05 *M* KH_2PO_4 at 25° C. (gas phase: nitrogen).

	0·055 *M* Glucose	0·019 *M* Fructofuranose	0·252 *M* Glucose	0·446 *M* Glucose	0 041 *M* Fructofuranose
Sauternes yeast	58	100	64	64	96
Brewer's yeast	88	88	100	100	100

These differences between brewer's and Sautern yeasts in their behaviour towards the aldehyde a the keto sugar disappear completely when dri preparations of the yeasts are used. The curves the accompanying figure show that at 0·053 *M* initi phosphate concentration both with dried brewe and with dried Sauternes yeasts the ratio of t maximum fermentation rates of fructofurano (0·05 *M*) and of glucose (0·40 *M*) is approximately 1·



Rates of fermentation of glucose (0·40 *M*) and of fructofuranose (0·05 *M*) by dried brewer's and Sauternes yeasts (1 gm.) at 0 053 *M* initial orthophosphate concentration. All samples contain 3 mgm. acetaldehyde and 0 8 ml. toluene. Total volume, 10·6 ml. $pH = 6 \cdot 2$. Gas phase: carbon dioxide. Temp. 25° C.

With inorganic phosphate and sugar concentratio high enough to provide optimal conditions for t reaction: 3-phosphoglyceraldehyde + phosphate cozymaze $\rightleftharpoons$ 1,3-diphosphoglyceric acid + dihydr cozymase, the small difference in the maximum rat of fructofuranose and of glucose fermentation dried yeast preparations is probably due to differe rates of the hexokinase reaction with fructofurano and with glucose. It would appear that in the presen of excess substrate the turnover of the phosphoryl tion of fructofuranose by hexokinase is about 10 p cent greater than that of glucose. The greater activity of fructofuranose with hexokinase reve itself most noticeably at low concentrations of t substrate. Thus using dried brewery yeast a 0·081 *M* phosphate concentration, with fruct furanose half the maximum velocity was attained 3×10^{-3} *M* concentration, as compared with gluco at $7 \cdot 2 \times 10^{-3}$ *M* concentration. This is in clo agreement with the results of previous measuremen showing that the ratio of the dissociation constant the hexokinase-glucose complex to that of the hex kinase fructofuranose complex is approximately 2.

These results allow of a common interpretation the initial step in alcoholic fermentation of *d*-gluc and *d*-fructose by different types of yeast, which w previously scarcely possible[6,7,5,6]. In view of t close approach of the maximum rates of fermen tion by dried Sauternes yeast of fructofuranose a of glucose (in higher concentrations) the differen in those rates exhibited by living Sauternes yeast best explained as due to differences in the permeabil of the membrane of the living cell for the two suga The same enzyme, hexokinase, is concerned in t primary attack on *d*-fructose and *d*-glucose irresp tive of the type of yeast. A marked difference, ho er, exists in the interaction between hexokinase d the two substrates. While all the components of *d*-glucose solution at equilibrium react with hexo- nase, of the various *d*-fructose modifications only at fraction present in the furanose form serves as bstrate. This very reactive and labile substance s about twice the affinity of glucose for hexo- nase. If fructofuranose and glucose compete for xokinase, as they do in the fermentation of invert- gar, the relative rates of disappearance of fructose d glucose from the medium depend on the relative ncentrations of fructofuranose and of glucose inside e cell and their relative affinities for the common zyme. While at room temperature with brewery d baker's yeasts the much higher concentration of e aldehyde sugar within the cell outweighs the eater affinity of fructofuranose for hexokinase elective fermentation of glucose'), in the case of uternes yeast the greater permeability of the cell embrane of this yeast for fructofuranose plus the gher affinity of this sugar for hexokinase result in e 'selective fermentation of fructose'.

It seems to be noteworthy that *d*-fructose, when king part in the biological formation of fructose-6- osphate, fructose-1,6-diphosphate, aldosido < > ctosides and polyfructosides, always reacts in the bile furanose form. This may suggest an interpreta- n of the central role assigned to *d*-fructose in the etabolism of carbohydrates.

Full details will be presented elsewhere, including more complete survey of the literature.

MELLON INSTITUTE OF INDUSTRIAL RESEARCH

ANNUAL REPORT

HE thirty-second annual report of the director, Dr. E. R. Weidlein, to the trustees of the Mellon titute of Industrial Research, Pittsburgh, Pa., ers the year ending February 28, 1944, and the rd year of war research at the Institute. Research l advisory collaboration with the War and Navy partments grew in scope and value during 1944–45, well as investigations and other technical help the War Production Board, Rubber Reserve npany, National Defence Research Committee the War Metallurgy Committee of the National demy of Sciences. During the year in question, ety-four industrial research programmes were in ration, of which fifty-four were multiple fellow- s ; this does not include seven fellowships the vities of which stopped for the duration of the r. Of the ninety-four fellowships, three have n proceeding for thirty years and four others for nty-five years ; twenty-two have been proceeding more than ten years, and twenty-seven have been peration for five years. During the year 1943–44, Institute's expenditure for pure and applied arch amounted to 2,042,385 dollars ; 244 fellows were employed, together with 232 research associates and assistants, laboratory assistants and technicians.

From the long list of investigations mentioned in the report it is possible to select only a few for mention. In the physical field an investigation has shown the potential speed of a process for separating gas mixtures by diffusion into a fast streaming vapour. Methods for measuring surface areas of porous adsorbents have been studied critically and a method published for determining thermal conductivities at low temperatures. An investigation on frictional losses in vaned elbows of asbestos ducts has led to these losses being reduced to an absolute minimum. Research on the treatment of dry air-set mortars so as to prolong the period during which they may be stored has led to products which may be stored about four times as long as the present material, and the manufacture of products such as 'Garcrets', 'Garspar', and 'Gartex' has been improved in efficiency. A new process devised for the manufacture of 'Garsand', a promising glass batch ingredient, will form the basis of an extended programme. A combination limestone-lime process which offers substantial saving in many localities has been developed for treating waste pickle liquor, and current investigation indicates that magnetic iron oxide of pigment quality can be obtained from waste pickle liquor by a simple process with low operating costs.

A study of the impurities in nitration benzene indicated that the principal contaminants are naphthenes, some of which have boiling points as much as 20° above that of benzene. A rapid and accurate method has been developed for determining hydrogen cyanide and its derivatives in the gaseous, liquid or solid state, as well as a new process for making guanidine nitrate. Investigations on the rheological properties of tar products have led to the manufacture and introduction of a pitch compound of modified flow characteristics, suitable for protecting metal products such as corrugated roofing and siding, flat and V-crimp sheets and associated constructional accessories. A process has been discovered for vinylnaphthalene, which has promise in plastic technology, and progress has been made in the synthesis of picolines and vinyl derivatives of pyridine and in the oxidation of lutidine and picolines. The synthesis and properties of 1 : 1 : 3-trimethylcyclopentane, a new hydrocarbon, have been described. The identification of some fifty alkylated phenols, based on the properties and X-ray diffraction spectra of their phenyl *iso*cyanate derivatives, has been published. Much attention has been given to the development of improved synthetic lubricants for aircraft instruments, and a high-quality product has been developed. Lubricating oils for watches and similar fine mechanisms are also being investigated, as well as the production of chemicals for improving hydraulic fluids and low-temperature lubricants for the Armed Forces, while collaborative testing of extreme pressure addition agents has been carried out for a Government agency.

A study of the proteolytic enzyme activity in chicken eggs has been concluded and an economic process for drying yeast will soon be in operation. Fundamental advances have been made in the programme on cotton properties, and other investigations in the textile field have covered sizes for knitted hosiery, resin coating for fibres, and new treatments of woollen felts against heat, water, chemicals and abrasion.

Special reference is made in the report to the investigations of the Department of Research in Pure Chemistry on the synthesis of new anti-malarials, particularly the application of the novel hydroxyethylating agents, and a hydroxyethyl analogue of 'Pamaquin' has shown considerable promise. Sulphur derivatives of quinoline have also been prepared, as well as ten new bases of 2-styrylquinoline type in which a modification of Brahmachari's method raised the yield from 2·5 per cent to 80 per cent. Conditions have also been established for the formation of the *p*-dialkylaminobenzylidene diquinaldines, and four new 4-*p*-dialkylaminostyryl-quinolines have also been prepared as well as 6-hydroxyethoxylepidine and the corresponding 6-hydroxy derivatives. The pharmacological properties of the hydroxyethyl-ether derivative of morphine have been determined, and an intensive search made for morphine derivatives free from the medically undesirable side-effects and less liable to cause addiction. The Institute is also participating in the thirteenth revision of the Pharmacopeia of the United States, which is now under way.

Studies of the physical and chemical properties of synthetic racemic menthol have been published, and a method developed for determining iodine in organic compounds. The Institute is also co-operating in an important investigation of chemical methods of analysis for the highly insoluble glass required for ampoules for penicillin and organic arsenicals.

A RADIO NAVIGATIONAL AID

A NOVEL method of position-finding by the aid of long radio waves, applicable to both aerial and marine navigation, has been developed to practical utility during the War by the Decca Record Co., Ltd.

The system uses two or more fixed transmitting stations which radiate signals of constant frequency and amplitude in all directions along the ground. At the receiving point the difference in phase of the waves arriving from two stations is measured, and it is then known that the receiver is on one of a number of hyperbolic curves, which are the loci of points of equal phase difference from the two transmitters. By repeating the observation on the signals from a third station compared with one of the first two, the position on an intersecting series of curves is found, and so the exact location of the receiver is determined. The phase comparison must be carried out on signals of identical frequency, but since only signals of different frequency can be received separately, the transmitting stations operate on different frequencies having a common harmonic relationship, and the necessary restoration to a common frequency for measurement purposes is carried out in the receiver itself.

In the development of the Decca Navigator system, great care has been taken to secure adequate frequency control of the transmitters and also of the reference oscillator in the receiver, which has been designed around radio circuits of high stability. The actual measurement of phase is carried out with a special meter which, by means of a train of gears and suitable indicators, displays a direct reading of the phase difference for transfer to the chart supplied for use with the instrument. Various precautions have been taken to render the whole system free from variations of phase of the signals due to instr mental changes, and the sites of the transmitti stations are selected so as to avoid so far as possib any effect of varying ground conditions on the pro agation of the radio waves used. It is claimed th at a range of 300 miles, the navigating system accurate to about 200 yards, and for shorter rang it is more accurate still. Much greater ranges a possible for daylight working, but during the nig the effect of ionospheric waves superimposed up the ground waves may limit the range at which t highest accuracy can be obtained.

During the War the system was used by t Admiralty; and it has now been disclosed that was used from *D*-day onwards to guide the leadi minesweepers and landing flotillas. The system likely to have peace-time applications to both and marine navigation.

EXCHANGES OF INORGANIC ION THROUGH LIVING MEMBRANES

THE large differences in concentration of sing ions (especially potassium and sodium) betwe living cells and their surroundings were discussed the Croonian Lecture of the Royal Society*. The differences are generally maintained by transp work through the surface layer making good t simultaneous diffusion losses.

Membranes differ greatly in permeability as sho by selected examples. The blood vessels of the ver brate central nervous system in particular show ch acteristics of permeability approaching those of t surfaces of many cells. They are highly permea to water and lipoid-soluble substances, but o slightly permeable to crystalloids including ions.

A number of examples were given demonstrati the active transport of ions through membranes co posed of cells (plant roots, gills of aquatic anima intestinal epithelium, etc.) and into (or out individual cells (giant plant cells, root cells, eryth cytes, striated muscles, etc.). All the cells stud are freely permeable to water, but the differe between mechanically supported plant cells and na animal protoplasts was emphasized. The latter m always be in osmotic equilibrium with their roundings, while the former can build up a surp pressure by active absorption of ions.

In the case of plant roots, the energy expended absorbing anions is considerable; but in animal c the permeability is so slight that the energy exchan involved in active transport cannot be measur In several cases the process depends upon the acc to glucose or oxygen or both.

In cases where an active transport takes pl the passive permeability can only be measured means of isotopes and only when special conditi are maintained. Several experiments with isoto have been recalculated to give absolute permeabi figures, and these show for erythrocytes and mus higher values for sodium than for potassium, a re incompatible with a simple pore permeability, supporting the Lundegårdh conception of mo surface films of the Langmuir pattern.

---

* Abstract of the Croonian Lecture "The Active and Pa Exchanges of Inorganic Ions through the Surfaces of Living and through Living Membranes Generally", delivered by Prof Au Krogh, For Mem.R S, before the Royal Society on October 25. Lecture should have been given in 1940, but Prof. Krogh was unable to travel to England.

COSMIC RAYS

ANGLO-FRENCH CONFERENCE IN BRISTOL

AN Anglo-French Conference on cosmic rays was organized by the Physics Department of the niversity of Bristol, with the collaboration of the ritish Council and of the French Government, hich made it possible for about fifteen delegates om Paris and other French universities to attend. he discussions took place in the H. H. Wills Physical aboratory during September 25–27, and were tended by about sixty physicists, including Prof. F. oliot, Mme. Joliot-Curie, Dr. P. Auger, Prof. P. A. M. irac, Prof. P. M. S. Blackett and Sir George Thomon. The conference was the fourth in the series of ternational physics conferences in Bristol—others ere held in 1935, 1937, 1939—and was one of the rst international gatherings of its kind since the War.

The conference was devoted mainly to discussions n cosmic rays and certain aspects of nuclear physics. n his opening remarks, Prof. N. F. Mott, after weloming the French delegation, stressed the importance f such conferences, and expressed the hope that others f a similar character would follow. They would onstitute an important contribution to re-establishg that international collaboration between scientific orkers which has been so seriously hampered by e War and is of such decisive importance for the lvancement of knowledge and understanding beween peoples. During the past five years the work both French and British men of science has been rgely interrupted by the German occupation of rance and, in Britain, by preoccupation with shortrm war-like applications; the main object of the nference was thus to survey rather broadly the resent position in our knowledge of the cosmic rays, d to exchange views on the main problems awaiting lution.

In introducing the discussion on the cosmic rays, rof. P. M. S. Blackett pointed out the importance a clear recognition of the difficulties encountered y the present theories of nuclear forces and of highergy particles. He said that in this field at the oment theoretical physicists are very experimental their search for a satisfactory formalism, and that til some of the major difficulties have been resolved, perimenters should avoid attaching too much eight to theoretical conclusions.

In a review of researches on cosmic rays carried t during the War, Dr. L. Jánossy said that at sea-vel the cosmic radiation consists of at least three mponents; the soft component consisting of posive and negative electrons, the hard penetrating mponent of mesons and a very penetrating comnent of low intensity consisting probably of prons and neutrons. The mesons must be of secondary igin because of the short mean life-time, 2×10^{-6} c., between their formation and disappearance with e emission of a fast electron.

Wataghin and his co-workers, and, independently, nossy and Engelby, have established the existence showers containing several penetrating particles. e air-lead transition of such showers has also been vestigated by Jánossy, and the effects observed n be interpreted as due to the production of mesons the impact of fast protons and neutrons on the d nuclei. The magnitude of the effect and other tures of the observations are in satisfactory agreent with the theory of Hamilton, Heitler and Peng.

In a paper on the meson theory, Prof. W. Heitler pointed out that the short-range forces between the nucleons, that is, the neutrons and protons, which are responsible for the fact that the ordinary nuclei are stable structures, can be explained only in terms of a new kind of field, the meson field. Each nucleon is regarded as being surrounded by a meson field analogous to the electromagnetic field in the case of charged particles. In the meson field theory, the mesons, first postulated by Yukawa, are analogous to the quanta of the electromagnetic field theory, but are distinguished in that they may be charged, positively or negatively; that they have a finite rest-mass and a short life-time. Just as in the case of the hydrogen molecule the cohesion of the two component atoms is due to the exchange of electrons between them, the so-called exchange force, so the force between two nucleons is to be attributed to the exchange of mesons between them.

In the development of the meson theory the interaction between mesons and nucleons was first treated in a way analogous to the interaction between electrons and radiation. The results so obtained were, however, in sharp disagreement with the cosmic ray observations. The discrepancy appears to be due to a neglect of terms corresponding to radiation damping. In the electromagnetic case, in treating the interaction between an electron and an electromagnetic field, this term is very small and can be ignored. On the contrary, it appears to be of great importance in the meson theory. Hamilton, Heitler and Peng succeeded in developing a method of taking account of the radiation damping term, and thus obtained reasonable values for the cross-section for processes involving the collisions between mesons and nuclei. In particular, a large body of experimental facts can be accounted for in terms of the emission of mesons in the collisions between nucleons. In this way a satisfactory picture of the main features of the hard component of the cosmic radiation can be drawn, if we assume that the primary particles entering the high atmosphere are protons and neutrons, which soon collide with nuclei and thus generate fast penetrating mesons. The soft component consists of electrons produced by photons in the well-known cascade process involving pair production, but the relation between the soft component and the primary particles is not yet clearly established. The agreement between the theory and the experimental observations on the hard component is remarkably satisfactory when it is considered that the necessary constants in the theory are not arbitrary but have been determined from nuclear parameters by Möller and Rosenfeld.

A. Rogozinsky described experiments to demonstrate the existence of mesons in the extensive Auger showers. Certain of the showers were shown to contain a single penetrating particle. During the discussion, photographs were shown of the end of the track of mesons and the fast electron emitted in their decay, as obtained with the high-pressure expansion chamber developed by the late Prof. E. J. Williams. M. Tsien also showed a scientific curiosity in the form of an expansion chamber photograph obtained by Dr. Ho, a young Chinese colleague. The photograph, taken in a magnetic field, shows a positive electron colliding with an ordinary electron without annihilation in the process; the positron recoils, having given most of its energy to the recoiling negatron. Papers on the height of formation of mesons by A. Fréon, and on the measurement of the mean life-time of mesons by M. Maze, were also given. It is found, on the basis of reasonable assumptions about the energy distribution of the mesons created by an initially isotropic primary radiation, that the height of formation of the mesons observed at sea-level is considerably lower than that point in the atmosphere where the meson component has its greatest intensity. This indicates that the observed mesons have been created at a considerable depth in the atmosphere. The observations of the mean life-time of the mesons obtained by M. Maze is in satisfactory agreement with the work of other observers. The hypothesis of a multiplicity of mesons of different mass seems to be unnecessary.

The discussion on various aspects of nuclear physics was introduced by Mme. Joliot-Curie. By an extension of the methods of Bohr and Wheeler, and using recent experimental values for the mass defects, the stability of isobaric nuclei can be studied in some detail. It is possible to determine from the resulting curves whether the elements formed in the fission process, which give rise to the succession of β-emitting bodies, have an odd or an even mass number. The method also gives valuable information about the energy of the resulting continuous β-ray spectrum.

A review of the present stage of development of the photographic method of making visible the tracks of heavy ionizing particles was given by Dr. C. F. Powell. Suitable emulsions are able to record slow mesons as well as protons, deuterons, α-particles and heavily ionizing nuclear fragments. The energy of homogeneous groups of protons and deuterons can be determined, in the absence of serious background fog due to γ-rays, with an error of the order of ± 30 ekv., but the energy of an individual particle is subject to errors of ± 0·3 Mev. In the case of fast protons the orientation in the emulsion of the original direction of motion of the particle can be determined with an accuracy of about 1°.

Some typical results to show the precision obtained with the method were displayed, including measurements on the scattering of fast neutrons by protons and on the angular distribution of the particles resulting from the bombardment of gas targets of the light elements by beams of fast protons and deuterons from the Liverpool cyclotron. The main technical problem remaining to be solved is the improvement in the quality of the emulsions to make possible the employment of unskilled observers in the microscopic examination of the plates.

M. Frilley described experiments on the determination of the wave-length of γ-rays, with especial reference to nuclei of the actinium family, which showed that there are a number of anomalies in the internal conversion coefficients. It has long been known that certain radiations are almost totally internally converted so that they appear with vanishingly small intensity. Frilley showed that the contrary effect also exists in the case of certain γ-ray lines, which appear to produce practically no secondary electrons from the parent atom. No satisfactory theoretical explanation of this phenomena appears to have been found. Other anomalies also occur in the X-ray spectra excited in the radioactive elements during disintegration and studied by different methods. Whereas the differences $K\alpha_1 - K\alpha_2$ correspond well with our general conceptions derived from X-ray spectrography, the corresponding energy differences as deduced from measurements on the internally converted electrons indicate a bigger energy interval.

In experiments on the γ-rays from radium D Tsien, by measuring the ranges of the photo-electron produced in the Wilson chamber, has found a radiation of 23·3 ekv. which is equal to half that of th well-known line at 46·7 ekv. The new line is thu partially masked by the second order of the mai line in diffraction measurements. He also finds radiation of 7 kev. which is of lower energy than tha of the natural L radiation. Tsien stated that i the cases where one finds abnormally high intensitie of the L lines, as in the case of actinium and radiun D, this is probably associated with the interaction o the low-energy nuclear electrons (< 20 kev.) wit the L shell of the atom in question.

J. Surugue described experiments on the study o the secondary β-rays from the actinium family whic is complementary to the work of Frilley on the γ-ray

Lecoin mentioned that certain trajectories of primary electrons from radium E show abnormally hig scattering. Further experimental work on this subject is in progress.

A paper on nuclear isomerism by R. Berthelc dealt with a continuation of Pontecorvo's work o Br^{80}. The metastable level of Br has a period 4·5 hr. The transition to the ground-level is accompanied by the emission of a quantum of energy 49 kev which is completely converted internally, and b another of 37 kev. which is partially converte Berthelot concludes that the metastable level is 8 kev. above the ground-level, the transition to th ground-state taking place in cascade through a intermediate level. The two radiations follow or another within a period of less than $2\cdot3 \times 10^{-8}$ se The 49 kev. radiation is, in the view of the author, magnetic octopole, and the 37 kev. line a magnet dipole, radiation.

In a very interesting paper by Prof. Dupouy, a account was given of an electron microscope usin magnetic focusing, which gives very high resolvir power. It was mentioned by the author that a ne instrument, using protons instead of electrons, is course of construction in the Collège de Franc which it is anticipated will give a substantial increa in resolving power over that at present available.

RECENT EARTHQUAKES

DURING April 1945, three strong distant eart quakes were registered by the instruments Auckland, Arapuni, Christchurch and Wellingto New Zealand. These occurred on April 15, 19 and 2 the epicentres being unknown until results are hand from other observatories in the Pacific zon Six earthquakes were actually felt in New Zeala during the month, the largest being on April 1 wi epicentre near lat. 35° S., long. 178° W. The sho on April 7 was felt at Mapua, that on April 17 Wairarapa and Wellington, and that on April 23 Masterton.

During the same month, twenty-three earthquak and tremors were registered on the instruments Toledo in Spain. The greatest was on April when an earthquake from an epicentral distance 112·5° registered a full suite of waves, and attained maximum ground amplitude of 50 μ on the nort south component at Toledo. *The Times* reported earthquake felt over a wide area in the Province Alicante on July 2, the shock being felt most strong near Onteniente, where shocks occurred about thr ars ago. There is no report of any damage, and rther details of this shock are awaited from Spain. The United States Coast and Geodetic Survey, in -operation with Science Service and the Jesuit ismological Association, has determined the epi- ntres of the earthquakes of May 19 and June 3. he former, from the readings of seismograms tained at sixteen observatories, had an epicentre ar lat. 40·2° N., long. 126·8° W., which is off rthern California. The latter occurred at 13h. ·6m. G.M.T. from an epicentre near lat. 8·3° N., ng. 82·6° W., which is in Chiriqui Province, Panama.

During April, May and June nineteen earthquakes ere registered on the seismographs at King's College bservatory, Aberdeen, Scotland. The strongest of ese was on May 19, when an earthquake regis- red at 15h. 18m. 34s. G.M.T. and attained a maxi- um ground amplitude at Aberdeen of 20 μ on the rth-south component.

At Binstead, Isle of Wight, Mr. E. W. Pollard gistered eleven earthquakes during June; his achine was undergoing repairs during June 26 d 27.

CLOSURE AND PARTIAL SEPARATION OF A METALLIC CONTACT

THE problems associated with contacts between nominally clean metallic surfaces approaching d separating normally may be divided into two oups according to whether the path between the rfaces is metallic or gaseous. A paper by Dr. Alan irweather (*J. Inst. Elec. Eng.*, 92, Pt. 1, No. 56; igust 1945) is concerned with the first of these oups. The field of interest may be further sub- vided, as it includes both the phenomena associated th nominally static contacts and those relevant to parating contacts up to the instant when the metallic th between the contacts ceases to exist.

In the first part of the paper, all the effects en- untered in the change of resistance with current d mechanical pressure are shown to be predictable the basis of the existence of contact spots. The tents of resistance changes are directly related to e mechanical pressure. A fresh technique is scribed, by means of which the existence of the ots may be demonstrated and a lower limit assigned their number. The influence of the rate of current ding is examined, and further verification of the stic character of the yielding process is furnished. e measurements described relate to one particular tact material, a platinum iridium alloy, and to surface finish. They cover much wider ranges pressures and voltages than are encountered in ctice, and permit identification of all the significant nts observable in a normal laboratory atmosphere. is range of observations is bounded only by limits which effects cease to be those relevant to a clean tallic contact. One limit, attributable to surface ns, not necessarily due to tarnishing, is encountered very small pressures and voltages: the other ears at higher voltages which, if exceeded, result mately in glowing and fusion of the contact sur- es.

he second part of the paper is concerned with unequal wear of the two members of a contact r, termed 'selective erosion' or 'unbalanced erosion'; is frequently accompanied by a gain of material by one member at the expense of the other. In severe cases one member may develop a large pip while the other produces a corresponding crater: the contacts may then lock together. Hitherto, experience has suggested that such pips and craters occur in a random manner and that neither seems to be associated with a particular contact polarity. The work described presents a new and simplified approach to the problem. It is suggested that, in general, and perhaps more especially when quenching is permissible, unbalanced erosion results from, or can be made to result from, two main causes: first, the molten metallic bridge joining the contacts when only partly separated, and secondly, the arc. The sense of arc erosion is always the same, independent of the metal, whereas that of bridge erosion depends on the sign of the Thomson coefficient of the metal near its boiling point. Thus, metals for which the senses of the bridge and arc erosion are the same can only exhibit one sense of erosion; but those for which they are opposite can exhibit both senses, or even none at all, depending on which effect predominates due to appropriate circuit conditions. This leads to the idea of alloys so designed as to possess a zero Thomson coefficient near their boiling point, which would therefore give equal bridge erosion of both contact members. Progress has been made in the development of such alloys. The remaining unbalanced arc erosion would then be reduced as far as possible by the use of an appropriate quench. Such alloys would, of course, have to satisfy all the conventional requirements for contact materials and, if possible, one more: even with a quench, the possibility of slight residual arcing cannot be neglected, so that it would be desirable, when selecting metals for the development of balanced bridge erosion alloys, to do so from those which do not readily support an arc.

FORTHCOMING EVENTS

Saturday, November 3

ASSOCIATION OF AUSTRIAN ENGINEERS, CHEMISTS AND SCIENTIFIC WORKERS IN GREAT BRITAIN (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 3 p m.—Meeting of British and Austrian scientists in support of the restoration of Science in Austria.

Monday, November 5

FARMERS' CLUB (at the Royal Empire Society, Craven Street, Strand, London, W.C.2), at 2.30 p.m.—Prof. T. Dalling: "Sterility in Cattle".

SOCIETY OF ENGINEERS (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. M. Spindel and Mr. R. T. Quinn: "Improvements on Portland Cements and Concrete —Past, Present and Future".

Tuesday, November 6

BRITISH PSYCHOLOGICAL SOCIETY, INDUSTRIAL SECTION (at the War Office Cinema, Curzon Street House, Curzon Street, London, W.1), at 1.15 p.m.—Lieut.-Colonel B. Ungerson: "Motion Study Applied to Military Problems" (with Film Illustrations).

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Dr. A. Muller: "50th Anniversary of the Discovery of X-Rays", (1) "The Background of Rontgen's Discovery".

QUEKETT MICROSCOPICAL CLUB (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Mr. E. A. Robins: "Trawler's Rubbish".

Wednesday, November 7

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W C 2), at 1.45 p.m.—Dr. E F. Armstrong, F.R.S.: "The Influence of the Prince Consort on Science" (Inaugural Address).

INSTITUTION OF ELECTRICAL ENGINEERS, RADIO SECTION (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. R. J. Clayton, Dr. J. E. Houldin, Dr. H. R. L. Lamont and Mr. W. E. Willshaw: "Radio Measurements in the Decimetre and Centimetre Wavebands".

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6 p m —Mr T. W. Goodwin and Prof. R. A. Morton: "The Determination of Carotene and Vitamin A in Butter and Margarine"; Mr. J. L. Bowen, Mr. N T, Gridgeman and Mr. G. F. Longman: "A Photoelectric Method of Assaying Vitamin A in Margarine".

Chemical Society (joint meeting with the Local Sections of the Royal Institute of Chemistry and the Society of Chemical Industry) (at the Newport Technical College, Newport), at 6 30 p.m. —Dr. E. H. Coulson and Mr J. L. Jones · "Research on Coal Tar".

Thursday, November 8

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m —Exhibit and Scientific Papers.

Royal College of Surgeons of England (at Lincoln's Inn Fields, London, W.C.2), at 5 p.m.—Mr. C. Max Page: "A Survey of Fracture Treatment" (Bradshaw Lecture).

Royal Institution (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Prof. James Gray, F.R.S : "The Anatomy and Functions of the Brain in Lower Vertebrates", (ii) "Amphibia and Reptiles".

Institution of Electrical Engineers, Installations Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p m —Mr. E. C. Lennox: "Street Lighting".

Society of Instrument Technology (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 6 p m.—Discussion on "Education in Instrument Technology".

Friday, November 9

Association of Applied Biologists (at the Imperial College of Science and Technology (Royal School of Mines), Prince Consort Road, London, S W.7), at 11.10 a.m. (in the Surveying Lecture Theatre), and at 2.15 p.m. (in the Metallurgical Lecture Theatre)—Discussion on "Factors Controlling Flowering" (to be opened by Prof. F. G. Gregory, F.R.S.).

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Scientific Papers.

Royal Institution (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Dr. W. K. Slater: "The Contribution of Science to Agriculture in War".

Institution of Mechanical Engineers (at Storey's Gate, St. James's Park, London. S.W 1), at 5.30 p.m.—Mr. H. O. Parrack: "Elementary Principles of Plant Organization and Maintenance for Civil Engineering Contractors".

British Association of Chemists, St. Helens Section (at the Y.M.C.A. Buildings, St. Helens), at 7.30 p.m.—Mr. S. W. Norman: "Fractional Distillation, the Theory and its Applications".

Saturday, November 10

Biochemical Society (at the London School of Hygiene, Keppel Street, London, W.C.1), at 11.30 a.m.—Discussion on "The Chemical Basis of Cell Structure and Function" (to be opened by Dr. J. F. Danielli and others).

Iron and Steel Institute (joint meeting with the Scottish Branch of the Institute of British Foundrymen) (at the Royal Technical College, George Street, Glasgow), at 3 p.m.—Mr. Basil Gray · "The German Steel Foundry Industry".

THE DISCOVERY OF X-RAYS

50th Anniversary Commemoration Programme

Inaugural Meetings

Thursday, November 8

At the Royal Society, at 11.30 a.m.
At the Royal Society of Medicine, at 4.30 p m.

Joint Meeting of all Participating Societies

Friday, November 9

At the Phoenix Theatre, Charing Cross Road, London, W.C.2, at 8 30 p.m.—Sir Lawrence Bragg, F.R.S.. "The Scientific Consequences of Rontgen's Discovery of X-Rays".

Medical Meetings

Friday, November 9

At the Royal Society of Medicine, at 10 a m.

Saturday, November 10

At the Institution of Electrical Engineers, at 2 p.m.

Scientific Meetings

Friday, November 9

At the Royal Institution, at 10 a m.

Saturday, November 10

At the Royal Institution, at 10 a.m.

Historical Reviews

Saturday, November 10

At the Institution of Electrical Engineers, at 3.30 p.m.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturers in Mechanical Engineering in the Department of Engineering of the Cape Technical College, Cape Town, South Africa —The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting C.2861.XA (November 8).

Principal of the Punjab College of Engineering and Technology, Lahore—The Ministry of Labour and National Service, Appointments Department, Technical and Scientific Register, Room 670, York House, Kingsway, London, W.C.2, quoting C.2854.A (November 10).

Engineering Assistant on the staff of the Buildings Department—The County Architect, Kent County Council, Buildings Department, Springfield, Maidstone (November 10).

Laboratory Technician in the Public Health Department—T Town Clerk, Finsbury Town Hall, Rosebery Avenue, London, E.C (November 10).

Chemist in the Soils and Plant Nutrition Section at Lo Ashton Research Station—The Secretary and Registrar, The Univ sity, Bristol (November 10).

Assistant (full-time) to teach Mechanical Engineering, Wor shop Practice, Engineering Science, Technical Drawing, a Mathematics, in the County Technical School, Newtown—T Director of Education, County Offices, Newtown, Mon. (November 1

Speech Therapist—The Director of Education, Stanley Buildin 3 Caunce Street, Blackpool (November 12).

Meteorological Officer Cadet, Department of Industry a Commerce, Dublin—The Secretary, Civil Service Commission, Upper O'Connell Street, Dublin (November 14).

Director of Industries, Bengal—The Ministry of Labour a National Service, Appointments Department, Technical and Scient Register, Room 670, York House, Kingsway, London, W.C.2, quot C.2862.A (November 15).

Assistant with qualifications in Agriculture for a survey Fertilizer Practice in the counties of Kent, Surrey and Sussex—T Secretary, South-Eastern Agricultural College, Wye, Ashford, Ke (November 15).

Science Graduate to teach Mathematics and Physics, and Graduate in Engineering or equivalent to teach Mathematics wi some Workshop Practice, mainly in the Secondary Technical Scho for Boys—The Principal, Southall Technical College, Beaconsfie Road, Southall, Middx. (November 15).

Lecturer (full-time) in the Department of Mechanic Engineering—The Principal, Borough Polytechnic, Borough Roa London, S E.1 (November 16).

Executive Engineers (4) by the Government of Bengal—T Ministry of Labour and National Service, Appointments Departme Technical and Scientific Register, Room 670, York House, Kingswa London, W.C.2, quoting E.2048.A (November 16).

Lecturer (Honours Graduate) in Chemistry—The Secreta Woolwich Polytechnic, Woolwich, London, S.E.18 (November 16).

Lecturer in Civil Engineering—The Director, Robert Gordo Technical College, Aberdeen (November 17).

Principal of the Dewsbury Municipal Technical College The Education Officer, Municipal Buildings, Halifax Road, Dewsbu (November 17).

Master (full-time) to teach Engineering Subjects, includi Applied Mechanics and Heat Engines, to Ordinary National Cert cate standard, and Engineering Science and Technical Drawi in the Junior Technical School, Newton-le-Willows Technical Sch —The Divisional Education Officer, The Gables, Crow Lane We Newton-le-Willows, Lancs (November 17).

Head of the Department of Zoology—The Registrar, Univers College, Hull (November 17).

Engineer and Manager to the Staffordshire Potteries Wat Board—The Clerk to the Board, 20 Stafford Street, Hanley, Stoke-o Trent (November 19)

Deputy Borough Electrical Engineer and Manager to t Borough of Willesden—The Town Clerk, Town Hall, Dyne Roa London, N.W.6, endorsed 'Deputy Borough Electrical Engineer a Manager' (November 19).

Psychologist to work under direction of County Psychiat primarily for County Child Guidance Service—The County Medi Officer, 4 Barnfield Crescent, Exeter (November 19).

Head of the Civil and Mechanical Engineering Department The Secretary, Woolwich Polytechnic, Woolwich, London, S.E (November 22).

Head of the Physics, including Telecommunications, Depa ment—The Secretary, Woolwich Polytechnic, Woolwich, Lond S.E 18 (November 22).

Lecturer in the Department of Physiology, University of C Town—The Ministry of Labour and National Service, Appointme Department, Technical and Scientific Register, Room 670, Y House, Kingsway, London, W C 2, quoting F.5050.X (November

Assistant Lecturer in the Department of Engineering—T Registrar, University College, Singleton Park, Swansea (November

Abstractors (male or female) for the Intelligence Section o Research Association—The Ministry of Labour and National Serv Appointments Department, Technical and Scientific Register, Ro 670, York House, Kingsway, London, W.C.2, quoting C.2856 (November 26).

City Electrical Engineer—The Town Clerk, Guildhall, Yo endorsed 'City Electrical Engineer' (November 29).

Borough Electrical Engineer—The Town Clerk, Town H Tunbridge Wells (December 31).

Assistant Electrical and Mechanical Engineer by the Gove ment of Iraq for the Basrah Port Directorate—The Ministry of Lab and National Service, Appointments Department, 1–6 Tavist Square, London, W.C.1, quoting F.A.52.

Assistant Laboratory Technician for the Physics Departm —The Warden and Secretary, London (Royal Free Hospital) Sch of Medicine for Women, 8 Hunter Street, London, W.C 1.

Assistant Lecturer in the Engineering Department of Mining and Technical College, Crumlin—The Director of Educat County Hall, Newport, Mon.

Biochemist with a good knowledge of Bacteriology to work on degradation of long-chain hydrocarbons by micro-organisms— Secretary, National Institute for Research in Dairying, Univer of Reading, Shinfield, Reading.

Head of the Engineering Department—The Principal, Techn College, Brunswick Road, Gloucester.

Lecturer (full-time) in Engineering—The Principal, Wa Technical College, Hartshill, Oakengates, Shropshire.

Lecturer-Instructor to teach mainly Motor-Vehicle Tech logy and Repairs, including Electrical Equipment and Repai The Principal, Medway Technical College, Senior Departme Gardiner Street, Gillingham, Kent

Principal of the Imperial College of Tropical Agricult Trinidad—The Secretary, Imperial College of Tropical Agricult Grand Buildings, Trafalgar Square, London, W.C.2.

ATOMIC ENERGY AND ITS UTILIZATION

NO one who has followed the trend of scientific opinion since the end of the War in Europe can mistake the growing emphasis which men of science in every country where the Press is free are placing on the restoration of full freedom of scientific intercourse, and the earliest and fullest possible relaxation of the secrecy imposed by the exigencies of war-time. Earliest in point of time, though not in publication, the Barlow Committee came out so far back as 1943 with strong recommendations regarding the fullest possible removal of secrecy restrictions, and the encouragement of publication and of discussion between scientific workers in different fields, within and without the Government service, above all in fundamental research. No feature of the Government's proposal for a scientific civil service is more welcome than the statement that these recommendations for relaxing secrecy are viewed sympathetically, and that scientific workers in the service of the Government will be encouraged to publish work of their own and to discuss their work with persons outside the service engaged on similar problems.

The report of Dr. Vannevar Bush, "Science : the Endless Frontier", published late in July, shows how scientific opinion in the United States of America has reached similar conclusions, and in one of its most important sections there are outlined concrete proposals for the restoration of scientific communications by international agreement. That report was published before the disclosure of the development of the atomic bomb ; but the visit of Allied men of science to the U.S.S.R. in connexion with the two hundred and fiftieth anniversary of the Academy of Sciences (see *Nature*, August 25, *et seq.*) left no room for doubt that scientific men in the U.S.S.R. are equally anxious for the resumption of contact and communications with their colleagues in other countries. Proposals which have come from Dr. J. Needham indicate that his work with the British Council's Scientific Office in Chungking has provided further evidence of a strong desire for the removal of war-time restraints and for full freedom of intercourse in science (see also p. 558).

This urge for full freedom of communication and the relaxation of the secrecy imposed by war conditions has been greatly strengthened both by the disclosure of the application of atomic energy in the atomic bomb and by the sudden termination of the War in the Far East. Whatever has been done so far to lift the veil on achievements in such fields as radar, 'Pluto', petroleum warfare and the like has in fact fostered, rather than abated, the demand for the full disclosure of the scientific work on which such developments are based. One reason for this may be seen in Sir Robert Watson-Watt's recent article on radar (*Nature*, September 15, p. 319) ; demonstration of the practicability and value of team-work in time of war stresses the importance of team-work for purposes of peace, and team-work is only possible when the exchange of knowledge is free and full.

There is a second reason why the demand for the relaxation of secrecy is growing. Revelations of achievements during the War again and again emphasize the way in which technical advance is bound up with fundamental research, and the extent to which advances in fundamental research proceed simultaneously and on parallel lines in different countries. It is clear from what has already been made known that the original researches in atomic physics from which the atomic bomb was developed were proceeding in various countries, and this knowledge was being freely published. This point is well brought out in the Smythe Report on Atomic Energy, which has now been published, and which looks to the publication, at least in part, of the papers withheld since April 1940. Sir Henry Dale was prompt to emphasize both that the preservation of civilization may depend on the fullest freedom of scientific intercourse and on the abandonment of any national claim to secrecy about scientific discoveries. That, he insisted, is a fundamental condition if international control of the atomic bomb is to be possible; and Sir Henry Dale was one of the first to emphasize that such control, as distinct from control of science or scientific research, is essential if we are to use atomic energy to full effect and avoid the disasters which must attend misuse.

That was the point of view which Mr. L. J. F. Brimble urged in letters to *The Statesman* of Calcutta (August 15 and September 7) during his recent visit to India and which it would seem, from editorial comment and from correspondence, Indian opinion is disposed to accept. Mr. Brimble challenged the practicability of the United States and Britain being able to keep secret the knowledge relating to the production and use of the atomic bomb. Legislation to control scientific research on uranium and other aspects of chemistry or physics related to the development of the atomic bomb would almost certainly be futile. The secret of any branch of research in atomic physics cannot remain the prerogative of any one nation or group of nations. Furthermore, if such control of scientific research were achieved, it would be a deadly blow to scientific progress and the advance of civilization.

Mr. Brimble distinguished clearly between the planning of science within the conception of freedom of the individual, and political control; but these two things are still frequently confused, as subsequent pronouncements in Great Britain and in the United States have shown. This confusion adds further point to Mr. Brimble's contention that our future progress depends both on a complete change of heart among nations and on thorough overhaul of our methods of education, so that every citizen acquires some appreciation of science and some insight into the impact of science on society. These are, in fact, the fundamental conditions for effective collaboration between statesmen and men of affairs, students of the humanities, spiritual leaders, men of science and others.

Further support for the view that it is impossible to maintain secrecy regarding the scientific developments leading to the atomic bomb has been forthcoming from Prof. J. D. Bernal (who, pointing o that secrecy would restrict the free flow of scienti information to the grave detriment of the recove of international science, urged that rapid progre could only come from the free exchange of inform tion) as well as from others in Great Britain a from various groups of American men of scienc The Association of Los Alamos Scientists, f example, comprising some four hundred of tho working there on the atomic bomb project, has be formed to promote the use of scientific and techn logical advances in the best interests of humanit and recognizes that scientific workers, by virtue their special knowledge, have, in certain spher special political and social responsibilities beyo their obligations as individual citizens. In co formity with this policy of releasing authoritati public statements on scientific questions in th relation to society, the Association issued a stateme on October 13 that there could be no keeping t secrets of the atomic bomb from the rest of the wor and that to attempt to do so would lead to w more savage than the last (see also p. 564).

The statement urged that the use of atomic ener must be controlled by a world authority and th such international control is technically feasib although it may involve the abolition of secrecy national and international relations and the provisi of free access to all laboratories, industries a military installations. It is the hope of the Assoc tion of Los Alamos Scientists in developing the bo that it will be a great force for world co-operation a peace. Lack of decision within even a few month the statement urges, may lead to unprecedent destruction.

These views have been substantially supported other organizations, such as the Atomic Scientists Chicago, who flatly challenged a report issued October 11 by the Naval Affairs Committee of t House of Representatives as contrary to exp scientific opinion. The Chicago group said th reports which suggest that effective counter-measu have been developed are misleading, and that sta ments attempting to minimize the importance of t atomic bomb and suggesting that armed forces w soon bring the situation under control would incalculable harm. The legislation which is be considered by this Military Affairs Committee been strongly opposed by both these groups scientific men as likely to retard research and development of atomic energy rather than stimul it. It is also feared that the proposed atomic ene control commission will prevent the exchange information between co-workers in the same labo tory, and that this, in accordance with the views the Barlow Committee in Great Britain, would d young men of science from the work, because transfer of information is vital to research in scien

The Association of Oak Ridge Scientists at Clin Laboratories, Tenn., composed of more than 90 cent of the scientific, engineering and technical st of the main research and development section of Plutonium Project, was formed late in Septem because its members felt they should take a gre ponsibility for the consequences of their handiwork. e Association was born out of fear that the wrong urse was being taken in regard to at least two ects of the atomic bomb. The first was the growing e sense of security prevalent when it was thought re was a secret formula for the atomic bomb held lusively by the United States and Great Britain. e second was apprehension that the atomic bomb s creating a feeling of fear among nations rather n of trust, and it seemed plain that unrestrained velopments in this field would only add to such r. This feeling of apprehension led to the view, d by a large portion of the membership of the ociation, that control of atomic power should be an international rather than national level, for it s felt that control of atomic power on a national el would lead inevitably to the greatest armament e ever known, and to increasing distrust among tions.

he activities of the Association so far have conted mainly of contributing to informed public nking in every way possible. Numerous statements ve been prepared by scientific workers who have en associated intimately with atomic bomb developnts, and the best of these have been endorsed by e Association and used as background material for lio and editorial comments, for Congressional arings and for personal contacts. If science is to controlled on a national level, the Association ieves that the inevitable armament competition l prevent science, especially 'nucleonics', from r being free again; and that scientific freedom as have known it will not again prevail until a lomacy of trust and good will is established among tions.

Dr. H. L. Anderson and Dr. Leo Szilard, on the er hand, have criticized the U.S. War Department publishing the Smyth Report on the development atomic energy, to which Lord Maugham referred the House of Lords on October 16. Dr. J. R. penheimer, who has just resigned his post as ector of atomic research at Los Alamos, declared ore the Senate Committee at Washington on tober 17 that the only defence against the bomb proper international organization, and Dr. H. J. rtis, representing scientific workers at the atomic oratories at Oak Ridge, Tenn., told the Comtee that the only solution to the secrecy problem o turn over to an international organization the trol of all aspects of atomic power.

nternational responsibility for the control and elopment of atomic energy was the theme of the ling article in *Nature* of August 11 immediately owing the dropping of the first atomic bomb. s, and the impracticability of secrecy, have been ssed many times since in these columns. But debate in the House of Lords on October 16 ws how, in Great Britain as well as in the United tes, political issues are liable to overlay and cone the scientific and technical aspects, particularly relation to the question of secrecy which we are v discussing. Nor was the position made clearer President Truman's early pronouncements; and d Maugham in the course of his speech did well to bring out the difference between attempting to keep secret the fundamental knowledge in atomic physics with which the development of atomic energy for any purpose starts, and the engineering technique involved in the production of the bomb itself. For the latter, indeed, it would be reasonable to argue for secrecy and the development of some effective means of control; but for the former, secrecy must be rejected as impracticable, as impolitic, and as contrary to the interests of science or humanity. It is clear from the debate in the House of Lords that there was general agreement as to the impracticability of secrecy in this respect; further, the Earl of Darnley found little support for his notion that adequate supervision of manufacture or the foreseeing or prevention of use of such weapons were equally impracticable. Rather, the opinion was that such control is difficult, but that it is absolutely imperative for appropriate means to be worked out with the utmost possible speed.

President Truman's address on American foreign policy delivered in New York on October 27 would seem to imply that he has at last arrived at similar conclusions; for he said: "We must find the answer to the problems created by the release of atomic energy—as we must find the answers to many other problems of peace—in partnership with all the peoples of the United Nations". Discussion of the atomic bomb with Great Britain and Canada will begin in the near future, and later other nations will be brought in. These discussions will look "towards a free exchange of fundamental scientific information"; but he emphasized that they will not deal with the processes of manufacturing the atomic bomb or other instruments of war. President Truman's pronouncements have met with some keen opposition even in the United States.

The issues were in fact more clearly displayed in the short debate initiated by Capt. Blackburn in the House of Commons on October 30. Capt. Blackburn strongly associated himself with scientific opinion that at the earliest possible moment we should get back to the peace-time exchange of scientific information, and in view of the impossibility of damming the river of knowledge, urged immediate internationalization of research and production in relation to atomic energy, and the calling of a conference of scientific workers as well as statesmen to recommend to the United Nations the best system of international control of atomic energy which can be devised. Sir Arthur Salter, quoting the points made by the American scientific workers already mentioned, and in particular Dr. Urey's declaration that peace-time application of atomic energy was of no importance unless the danger of atomic bombs was banished, stressed the urgency of the situation and pleaded for an immediate offer to place all information in the hands of the Security Council conditionally on an effective system of inspection. That plea for urgency cannot but be reinforced by the Government decision to set up a research and experimental establishment for atomic energy.

What has hitherto been lacking appears to be a convincing statement of the reasons why secrecy regarding the scientific aspects of the development and use of atomic energy should be dismissed forthwith from consideration as practical politics. It is generally recognized that so much is already known to many scientific workers in different countries that secrecy in this respect is a mere pretence. It has also been emphasized that restrictions in this field will only impede the scientific advance upon which the utilization of atomic energy for beneficial purposes depends. That is true, but Lord Addison went nearer to the mark when, in winding up the House of Lords debate, he expressed the opinion that it is not possible to circumscribe the activities of scientific research. The British Government has in fact consistently taken the right line in refusing to treat the atomic bomb as a special case. Mr. Bevin has insisted that it is not merely the atomic bomb but the whole advance of science in the field of war which must be controlled. Similarly, we cannot impose restrictions or secrecy in those branches of science which have contributed to the development of the atomic bomb without regard to the effect of such restrictions on scientific advance generally. We cannot predict from which field of science the next important advance may come, and to impose restrictions anywhere is to impede that interchange of thought, that cross-fertilization of minds and exchange of ideas from which all great advances have come without acquiring in return any solid assurance that investigations, of which we may know nothing, proceeding in other countries will not yield just the startling results that we dread.

Secrecy, therefore, is impracticable and contrary to the advance of science and the interests of humanity. No less important, secrecy in this field of scientific knowledge is impolitic as endangering that very confidence and good will which must be the basis of any organization for international control of the engineering technique of production for war purposes which is so vital and urgent. Nothing makes more powerfully for confidence and co-operation than the effective fellowship of scientific workers across national frontiers, the constant communication of each fresh advance as it is achieved and the interplay of minds engrossed in the search for truth over the problems and difficulties as they emerge. Nothing breeds suspicion and distrust more quickly than the withholding of new knowledge, the refusal to share it with others. It is not merely that scientific effort is wasted in duplication, or that the stimulating clash of minds is interrupted and the general advance of science is delayed. Perhaps even more important at this juncture is that, in place of co-operation and team-work, we have distrust and insecurity and a competition which can only result in disaster.

These are the reasons, therefore, why British men of science welcome the attitude of the British Government on this question of secrecy generally, and its refusal to treat the question of atomic energy as a special case. Mr. Herbert Morrison's statement on October 30 indicates no lack of appreciation on the part of the Government as to the urgency of the political and scientific issues involved, and in asserting the Government's intention to maintain a high standard of fundamental research and to plan m carefully the whole programme of research a development to make the best possible use of o resources, he gave welcome evidence of continu high interest in science and scientific workers. It clear that much remains to be done to educate publ opinion as to the critical importance of this issue, f it forms the starting point of an adequate policy ; a unless the implications which follow from this aba donment of a futile attempt at secrecy are realize we cannot expect the public in Britain or in ot countries to support their Governments in maki the sacrifices of national sovereignty that are involv in effective international control of the new weapo of war. Lord Cherwell was undoubtedly right maintaining that we could only hand over all t technique involved in such production to a bo which could be trusted to use it in the interests humanity; and the powers and organization of a such body have yet to be elaborated.

The House of Lords debate gave very little guidan as to the form or nature of any such organizati but both Lord Cherwell and Lord Addison we realistic and attempted to face the difficulties and find a genuine solution. As explicitly as the Bish of Chelmsford, Lord Cherwell recognized the need f a moral imperative, the over-riding need of findi means, at no matter what cost and sacrifice, reaching agreement without resort to force. Lo Addison quoted again the declaration of the Forei Secretary that "it is the aim of His Majesty's Gover ment that under the world organization we shou eliminate the desire to exploit the discoveries science for the purposes of war, and turn them i channels where they can serve the advancement humanity and human well-being". Holding that no apparatus for devising secrecy would humani be able to safeguard itself against this peril, he urg that our first effort must be directed towards creasing the international machinery which more a more puts a value on co-operation between natio and which more and more helps to remove the cau of distrust between nations.

That there should be so large a measure of agr ment among scientific workers as to the impract ability of secrecy in any field of science, and untoward effects on the advance of science and human welfare, is all to the good. Such recognit carries with it the responsibility of seeing that reasons for that attitude are understood by t fellow citizens. Above all, it must be demonstra that this is a positive and not a negative attitu that the abandonment of secrecy involves a fr effort to build the instruments and institutions effective control of the agencies of war in any fo and to create a moral imperative, whether in search for truth or in religious conviction, str enough to overthrow whatever forces of suspicion embedded prejudice or inertia, may stand in the w of the adoption of the means required to deal w the new situation with which these fresh advan in science have confronted mankind. Scient workers cannot be blind to the fact that there powerful forces opposing international co-operat and the exchange of scientific information, as the restrictions placed on the entry of British scientific and technical periodicals to parts of Germany and to Japan at the present time indicate. Never perhaps could they take to themselves more appropriately than at this juncture the words of Sir Francis Drake's prayer that in endeavouring such a great matter "it is not the beginning, but the continuing of the same until it is thoroughly finished, which yieldeth the true glory".

POVERTY AND POLITICS IN CENTRAL EUROPE

The Danube Basin and the German Economic Sphere
By Dr. Antonin Basch. (International Library of Sociology and Social Reconstruction.) Pp. xiv+272. London: Kegan Paul and Co., Ltd., 1944.) 18*s.* net.

Germany and Europe
Political Tendencies from Frederick the Great to Hitler. By Dr. F. Darmstaedter. Pp. vi+226. London: Methuen and Co., Ltd., 1945.) 12*s.* 6*d.* net.

DR. BASCH surveys in his book the economic problems of the Danubian States and their international repercussions—a subject of major importance for the period of reconstruction that has now begun, and one that has a vital bearing upon the future place of Germany among the nations. The book was written in 1943 and does not, therefore, take into account the important developments of recent months; but it provides a valuable study of the economy of a great region, extending from Czechoslovakia through Austria, Hungary, Yugoslavia, Rumania and Bulgaria, to Greece, and, though it concentrates on the key period of the 'thirties, it glances back to the situation before 1914 and makes some constructive suggestions for the future.

The work is authoritative, for Dr. Basch himself played an active part in many of the developments he describes. As a leading Czech economist he combined for some years a teaching post at the University of Prague with economic research for the National Bank of the Republic: later he became head of the Czech chemical industry and a member of the Economic Board of the Little Entente. He is mainly concerned with the political and economic opportunities that were missed in 1919 and subsequent years, and with the need for a better understanding of the Danube region's role in international affairs, for he is able to show only too clearly how the indifference of Britain and France to the economic problems of the region played into Germany's hands. But underlying all that he says of the economic activities of the seven countries, with their total population of nearly eighty millions, is an awareness of the human tragedy of economic backwardness which the Nazis exploited for their own ends. The consumption of food, and especially of protective foods, Dr. Basch points out, was "extremely low" throughout most of the region: only about one seventh of the agricultural area was devoted to protective foods, as against one third in western Europe. Yet foodstuffs and other agricultural produce had to be exported in order to buy essential raw materials and manufactured goods.

It was this situation, aggravated by the world slump in agricultural prices, by German agricultural protection, and by the indifference of the Western Powers (thus Britain, which before 1914 had bought Greek tobacco every year up to the value of £9,000,000, took only £20,000 worth in 1937), which gave Germany from 1934 the opportunity of using her purchasing power, through bulk buying, to turn the Danubian area into a dependent colonial, or semi-colonial, region, bound ever more closely to the Nazi military machine. German propagandists maintained that south-eastern Europe was the 'natural' sphere of German economic development and that the peoples in it would gain from their association with the Reich. In truth, German interest was rather in the military and strategic possibilities of economic control, as was made clear in 1941. Dr. Basch is able to show how heavily the bargain weighed against the Danubian peoples—and how little Germany gained, relatively, by her economic control. The conclusion is overwhelming that international, national and personal problems are indissoluble; that Europe cannot again run the risk of leaving the Danube area an agricultural slum. Peasant poverty and German hegemony are the same issues seen from different angles. The solution must lie in improved agriculture, with co-operative farming, in capital investment from abroad, in industrial development, and in the planned exploitation of natural resources. "An ultimate change in the economic and social status of this neglected region will provide a new and safer balance for Europe as a whole."

The nature of the German domination which turned peasant difficulties to its own ends is examined in Dr. Darmstaedter's book. He surveys the development of the German Power-State from the time of Frederick the Great, and sees it arising as the result of the weaknesses and divisions of German political life. Now National-Socialism has failed to give the German people the unity they have long sought, and a final solution of their problems can only be reached in a "European Commonwealth" in which Germany has an equal place. The argument is sound, if not always too clearly expressed: the conclusion would seem at the moment rather remote.

MAURICE BRUCE.

DEFICIENCY DISEASES IN BELGIUM

Les états de carence en Belgique pendant l'occupation Allemande 1940–1944
Par Lucien Brull, G. Barac, T. Brakier-Zelkowiecz, P. Clemens, R. Crismer, J. Deltombe, A. Divry, L. Dubois, L. Dumont, L. Dumont-Ruyters, A. Lambrechts, R. Neuprez, A. Nizet, M.-J. Op de Beeck, J. Piersotte et A. Thomas. (Institut de Clinique et de Policlinique médicales: Université de Liége.) Pp. 286. (Liége: Éditions Soledi; Paris: Hermann et Cie., 1945.) n.p.

THIS volume contains sixteen papers by different authors dealing with various aspects of dietetic deficiency as studied in Belgium during the years of German occupation.

Protein deficiency appears to have been the most important factor in the production of disease in war-time, and several papers are concerned with the effects of this deficiency on serum protein levels, œdema, etc.

Diseases due to vitamin deficiencies were little in evidence and the authors do not agree with the well-meaning theorists who advocated vitamin tablets where a square meal was wanted. Iron-deficiency anæmia and osteomalacia were likewise rare. The necessary vitamins, iron, etc., were obtained from whole bread and vegetables, and from milk and cheese, which were available for several months of the year.

Severe cases of Graves's disease were uncommon, and it is suggested that under-nourishment was responsible for this and outbalanced the opposite effects of increased emotional disturbance caused by the occupation.

Peptic ulcer was increased in incidence, largely due to emotional stress; but partly perhaps by the low fat-content of the diet. Other diseases of the gastro-intestinal tract were little affected in war-time except in that constipation was less frequent because of the diet comparatively high in carbohydrate and residue.

The last article would have been better omitted. On totally inadequate evidence the author cites infected scabies as the causal factor in a few cases of acute and subacute nephritis. Scabies has been so common all over occupied (and unoccupied) Europe that its presence in the cases described was almost certain to have been coincidental.

Belgium appears, on the whole, to have suffered less dietetic deprivation under the Germans than most of the other occupied countries; but, as Prof. Brull points out in his introduction, the conditions under which some of the authors had to work were iniquitous.

This interesting preliminary survey can only be recommended to those who read French, as the summaries in English which follow the articles are so condensed that they fail to convey the proper sense.

NATURAL ORGANIC COLOURING MATTERS

The Chemistry of Natural Colouring Matters

The Constitutions, Properties and Biological Relations of the Important Natural Pigments. By Dr. Fritz Mayer. Translated and revised by Dr. A. H. Cook. (American Chemical Society, Monograph Series No. 89.) Pp. 354. (New York: Reinhold Publishing Corporation, 1943.) 10 dollars.

THIS book will be warmly welcomed by all organic chemists who are interested in natural products. The colouring matters described are either of vegetable or animal origin, with the one exception of the organic mineral graebeite, a derivative of a polyhydroxyanthraquinone. The word 'Organic' would find an appropriate place in the main title of the book, and the subtitle would more accurately read "the Properties, Constitutions, and Syntheses of the Important Natural Pigments". There is naturally little discussion in the book on the biological relations of the colouring matters or of their mode of synthesis in Nature, as these are topics about which we possess extremely little knowledge.

The need for an up-to-date book dealing with this subject has been widely felt for many years, and it is natural to compare the present volume with A. G. Perkin and A. E. Everest's "The Natural Organic Colouring Matters", published in 1918. The advances revealed are most outstanding in our knowledge of the structures of the complex pigments of the carotenoid and porphyrin groups; in the carbocyclic and oxygen-heterocyclic series the advances are chiefly in the large number of new pigments which have been isolated since 1918.

In the foreword written by Dr. Mayer in 1939, th work is described as a completely revised text base on the second volume of the third edition of h "Chemie der organischen Farbstoffe", translated b Dr. A. H. Cook. The untimely death of Dr. May in 1940 and war-time difficulties delayed the pub lication of the volume, and the opportunity wa taken by Dr. Cook to revise the text to includ papers published up to the summer of 1941.

Chapter 1 contains a comprehensive account (8 pages) of the carotenoids, and this is one of the mos valuable sections of the book. Chapter 2 describ curcumin, the sole representative of the dicinnamoy methane class. In Chapter 3 (60 pages) are describe the carbocyclic colouring matters, which are near all derivatives of *p*-benzoquinone, naphthoquinone anthraquinone. The account of the many compoun containing a heterocyclic oxygen atom is given Chapter 4 (108 pages). Compounds containin heterocyclic nitrogen atoms are described in Chapter (71 pages); these include the pterins isolated fro butterflies' wings, a long account of the porphyrin and shorter accounts of the derivatives of indigo an pyrazine, the latter including riboflavine. Whe there are many pigments of the same type, gener descriptions are given of the properties and metho of synthesis of members of the group, followed b brief descriptions of the individual members. Th book contains more than two thousand references the original literature, and has an author and a fu subject index.

It may be doubted if it is wise to adhere too rigidl to the division of natural organic compounds in those which possess, and those which do not posses colour visible to the human eye. Such a distinctio is very artificial and has not been strictly followed the volume under review. For example, Chapt 4 includes descriptions of the colourless substanc flavone, catechin, cyanomaclurin and several othe presumably because of their similarity to relate coloured compounds; but the same liberality is n shown in the coumarin series, of which the so representative is daphnetin. Many naturally occurri coumarins are known, but they are largely of th phenol ether type and are colourless; had the happened to exist as free phenols, many wou have been coloured and would have receiv mention.

To the organic chemist this book is a well-stock herbaceous border showing every variety of colo and a few welcome colourless blooms. It would too much to expect to find no weeds among su profusion; but it is surely time that pentacovale nitrogen atoms and tetracovalent oxygen atom should be rooted out. Close inspection reveals moderate crop of accidental weeds, among whi may be mentioned a number of errors on pages 2 and 243, where the main reactions of brazilin a shown; vanillic acid (p. 229) is shown as *iso*vanil acid; hydroxyl groups are missing from formulæ pages 167, 201 and 205; flavane (p. 162) lacks phenyl group; purpurogallin (p. 103) is named its glycoside dryophantin. It is unfortunate that t most important method for the synthesis of flavon and flavonols, the fusion of an *o*-hydroxyketone wi the anhydride and the sodium salt of an aroma acid (Allan-Robinson), should have received menti only as an 'also ran'.

This is a valuable book, and it is to be hoped th it will be kept up to date by frequent furth editions.

W. BAKER.

A UNITED NATIONS EDUCATIONAL AND CULTURAL ORGANISATION

INTRODUCTION

By Dr. E. F. ARMSTRONG, F.R.S.

Adviser to Delegates of H.M. Government

THE United Nations Educational and Cultural Conference that opened in London on November 1 has been called to prepare the establishment of a United Nations Organisation for promoting educational and cultural co-operation.

It is natural that a new effort towards world co-operation in the cultural field should occur after the devastations of the Second World War. We wish to epair the damage to our friends and ourselves as quickly as possible.

This is particularly serious in the cultural field. The damage that the enemy has done to things of he mind is even more appalling than the terrible material destruction for which he is responsible. Vile deas have been instilled into the young, and the best traditions of research and learning have been debased.

The chief way by which the victims can be restored o civilization is by education and rehabilitation. It s, however, impossible to teach and to train the mind in research and rational inquiry without schools, and apparatus and laboratories.

One of the main aims of the Conference will be to create an Organisation that will help to achieve this estoration.

A second matter of equal importance is the promotion of educational, scientific and cultural co-operation in the future. Men of science will expect hat due weight should be given to science in the onceptions and machinery of the new Organisation.

The place of science in the structure and outlook of modern civilization has been growing steadily for enerations. Almost every aspect of production, ansport, nutrition, health and the primary needs of fe are dependent on it. The influence on modes of hought in research and learning, and spiritual ttitudes, is equally great. The application of the cientific mode of thought to the problems of man nd society is perhaps our chief hope for the future. ut we cannot utilize it if we do not know what it . We want to see the restoration and improvement f education, with appropriate weight given to cience, in view of its contemporary importance.

The latest developments of atomic energy make he need for the understanding and use of science ot a thousandfold greater.

Thus it is profoundly necessary that science should have due place both in the conceptions and aims of he new Organisation, and in its machinery.

The most perfect plan and organization will not work, however, without finance and public support, and these must be based on public approval.

Another point of equal importance is the question f priorities. It is essential that the Organisation ould be able to secure the needed equipment, after has acquired the adequate finance. Teaching and research cannot be done without apparatus, scientific erature, and communications.

Men of science throughout the world hope that the onference will have every success, and that, as a sult of the discussions, a new Organisation will be established which will strengthen existing scientific collaboration and create new links where they are needed.

SCIENCE AND THE UNITED NATIONS

By Dr. JULIAN HUXLEY, F.R.S.
